# Philo : National : Poultry Institute

## Learn to Make Poultry Pay

We teach poultry-keeping in all its branches by mail, or by demonstration at the greatest poultry institute in the world. The home of the

### Philo System

Fresh-laid eggs are considered the most perfect food, and any one can learn to produce them at a profit. With the improved methods taught in our schools

### A Successful Business and Good Living

may be had on a city lot or a small plot of ground in the suburbs, or in the country. Poultry-keeping is really a science. To get the greatest returns, all branches of the work must be thoroughly understood. A short course is all that is necessary to make the business a success, and to avoid the mistakes so common with those who do not understand the work.

### We can Teach You Scientific Poultry-keeping

by mail or at our National Poultry Institute, where thousands of the finest birds are raised annually. With our improved methods it is possible to handle the business with a very small capital, or students can get employment at good salaries.

Write for full information about our course of instruction in methods of poultry-keeping.

# Index to Gleanings in Bee Culture

## Volume XXXVIII

In using this index the reader should not fail to note that it is divided into five departments, namely, General Correspondence, Editorials, A. I. Root's Writings, Contributors, and Illustrations. The Index of General Correspondence includes everything except editorials and A. I. Root's writings.

### GENERAL CORRESPONDENCE.

Abandoning swarms caught in cold weather 451; Absorbent cushions best for damp winters 27; Absorbing cushions and sealed covers, meaning of term 629; Absorbing cushions preferred by those in extreme north 579; Absorbing cushions vs. sealed covers, Crane on 309, 579; Absorbent cushion v. sealed covers 60, 72, 120, 121, 200, 737; Absorbents v. sealed covers, Holtermann on 281; Acorns, honey from 532; Adulteration going on in California 749; Advertising by honey display 349; Advertising, F. J. Root on 699; Advertising, Foster on 593; Advertising honey by traveling men 592; Advertising honey, Hand on 650; Advertising honey in grocery papers 410; Advertising honey in parades 13; Advertising in magazines, Crane on 680; Advertising, local, Bonney on 558; Advertising, progressive, E. G. Hand on 784; Advertising proposed by National Association 732; Advertising, what will bee-keepers do about 440; Africa, bee-keeping in 685; Africa, bees in 462; After-swarm, how to prevent 60, 425, 476, 546; After-swarms with virgin queens 496; After-swarms 327; Alabama, bee-keeping in 595; Albumen in honey 68; Alexander apiary run by Frank Alexander 636; Alfalfa fails because bees do not fertilize blossoms 517; Alexander feeders, to prevent bees flying from 29; Alexander plan for black brood 650; Alexander plan for black brood failure 229; Alexander plan for black brood, Gibson on 125; Alexander plan for black brood, Grower on 144; Alexander plan for black brood, Miller on 68, 143; Alexander plan for black brood, Orton on 80; Alexander plan for black brood, Pressler on 141; Alexander plan for weak colonies indorsed 344; Alexander's plans, Lathrop on 484; Alfalfa and alsike not secreting nectar under same conditions 683; Alfalfa, bees used for fertilizing in Wyoming 565; Alfalfa, cotton taking place of in California 653, 756; Alfalfa frosted 406, 479; Alfalfa honey not liked in Texas 40; Alfalfa in Canada 548, 716; Alfalfa in Texas 37; Alsike and alfalfa do not secrete nectar under the same condition 683; Alsike, effect on mucous membrane 36; American bee-hives 488; American foul-brood, See Foul-brood, and Disease; Anger, none shown by pinched bees 748; Ant-proof hive-stand 700; Ants kept out of hives by oil painted near entrance 700; Apiaries, advantages of scattering 372; Apiaries cleaned up in spring 101; Apiaries, proper distance between 782; Apiaries, proper number of colonies in 782; Apiary, arrangement of 68, 442, 783; Apiary in California with hives painted red 613; Apiary located on hill 29; Apiary lost on account of flood 497; Apiary of badly confused bees 428; Apiary riddled with bullets 405; Atmosphere, effect of in California 405; Atmosphere, effect of on nectar secretion 479; Attic for bees 426; Attic the place for comb honey 612; Australia, bee-keeping in 734; Auto buggies, questions about 670; Automatic bee-brush 184; Automatic can-filler, Evans 489; Automobile for hauling honey 382; Automobile for out-apiary work 235; Automobile, kind needed by bee-keepers 372; Automobile, Scholl on use of for apiary 40; Automobiles come to stay 512; Automobiles, Crane on 173, 579; Automobiles for bee-keepers, Root on 454; Automobiles, medium-priced for bee-keepers 317; Automobiles used by extensive bee-keeper 316.

Baby nuclei, plans to prevent swarming out 308; Baling-wire to support foundation 427; Bait section in the center to prevent swarming 4; Bait-sections, to clean out at close of year 446; Bait sections, where to locate 22, 195, 299; Baits in center, do they mean drone

brood in sections 496; Baits used to start bees in supers 138; Baling newly mated queens 308; Bananas and bees 760; Basswood, history of 158; Basswood, scarcity of 280; Basswoods, how long before they yield nectar 533; Basswood, variation in time of blossoming 7, 70; Bee-bread, See Pollen; Bee demonstrations, pointers on 702; Bee demonstrator as interesting as a snake charmer 738; Bee demonstrator wearing only a bathing suit 759; Bee-journals, flat wrappers for 466; Bee-keepers' institutes in New York 200; Bee-keeping as a hobby 792; Bee-keeping, brains needed for 684; Bee-keeping by beginners, capital needed for 794; Bee-keeping, facts concerning profits in 614; Bee-keeping, F. Greiner's early experience in 56; Bee-keeping for farmers' wives 738; Bee-keeping in a town 20, 695; Bee-keeping, some slovenly methods 718; Bee-line not always a straight line 612; Bee-line, straight 720; Bee-louse 118; Bee paralysis, Beattie on 377; Bee paralysis, information wanted 411; Bees and color 559; Bees, are they semi-hibernators 585; Bees as fertilizers of blossoms 220, 251; Bees as inventors of the hive 478; Bees badly mixed 428; Bees cluster out in spite of ventilation 636; Bees, death of wintered outdoors 127; Bees frozen after a flood 199; Bees injuring fruit, Doolittle on 581; Bees in unirrigated portions of Colorado 340; Bees larger, would there be any advantage 780; Bees make expensive feed for chickens 681; Bees on shares 770; Bees on shares, who pays for extra labor 532; Bee-spaces, proper size of between supers 60; Bees, stingless 771; Bees that live all winter and then stored honey 497; Bees, three kinds found in same flower 756; Bee-stings for rheumatism, see Rheumatism; Bees, two kinds instead of robbers 801; Bees, why they run upward when hive is pounded, Bullamore on 788; Bees, young coming out of hive and dying 427; Bee territory control of 41, 154, 155, 157, 179, 191, 236, 752; Bee-tree colony united with weak colony in hive 668; Bee-tree, foul brood in 164; Beets, two thousand tons used per day in sugar factory 771; Beet sugar, are there any objections to 769; Beet sugar can not be sold from cane sugar 578; Beet sugar fed on large scale without bad results 733; Bee-veil, Chalon Fowls' 557; Beginners' first season 482; Beginner's mistakes and experiences 193, 228; Beginner's outfit, Todd on 796; Beginning in bee-keeping, Doolittle on 617; Bibliography of bee-keeping 46; Binding bee-journals 272; Bird sucks honey from bees 559; Bisulphide of carbon amount needed for fumigating 544; Black brood, see European Foul brood; Black color irritates bees 532, 545, 716; Blacks, are they immune to paralysis 412; Blacks breed untimely 339; Blacks do not surpass Italians 634; Blacks indorsed 392, 423, 680; Blacks, moths do not molest if strong 565; Blacks of Switzerland a distinct type 102; Blacks swarm less than Italians 298, 479, 766; Blacks, two kinds of 371; Blacks vs. Italians 424; Blacks vs. Italians for foul brood 58, 100, 102, 309, 511, 533; Black vs. Italian on sugar-cane 668; Bloating symposium on 269; Bloom four weeks early at Marengo 308; Blowing bees off combs 465; Bonaset as a honey-plant 737; Bookkeeping for honey-salesmen 422; Books for beginners 717; Bottom-bars, proper space under 164; Bottom-board, Hand's switch-board 693; Bottom-board, queen found under 623; Bottom-boards, should they be left on hives in cellar 801; Bottom rack to prevent comb-building 440; Boulder, Colorado, amount of honey sold in 750; Box-hive bee-keeping 466; Box-hives condemned by foul-brood laws 682; Box-hives,

importance of legislation against 618; Box-hives, no need of legislation against in United States 646; Breakfast food eaten cold 100; Breeder, how selected by Doolittle 211; Breeders, Scholl's method of selecting 246; Breeding, Bullamore on 788; Breeding from best colonies, Holtermann on 614; Breeding from best queens 308, 578; Breeding only from one queen in a season, Simmins on 582; Breeding, Simmins on 481; Breeding to increase the honey-crop, Howe on 699; Breeding to lengthen life 285, 512; Breeding, what has been accomplished in other animals 632; Brood-chamber, 8 v. 12 frame 354; Brood-chamber, higher temperature in than in super 714; Brood-chamber, Holtermann's arrangement of 312; Brood-chambers, Dr. Miller on 338; Brood-chambers, should the first honey be stored in 612; Brooder house, A. I. Root's 189; Brood-rearing in fall and spring 544; Brood-rearing, normal 452; Brood, skins of not fibrous 716; Brown bread made with honey 270; Buckling prevented by short splints 22; Buckling with 5-inch splints 68; Buckwheat-blossoms fertilized by bees 5, 245; Buckwheat, does fertilizer prevent secretion of nectar from? 465; Buckwheat field found by scent of bees 597; Buckwheat for grain and honey, McGowan on 151; Buckwheat growing in Ozark Mountains 378; Buckwheat-growing, Orton on 250; Buckwheat, Japanese not liked 360, 484, 514; Buckwheat, proof that bees fertilize 5; Buckwheat seed given away 92; Buckwheat, why it did not yield honey 533; Buckwheat, will it yield nectar in dry year? 596; Building up colonies 617; Bulk comb honey, Bonney on 376; Bulk comb honey editorial 174; Bulk comb honey gaining ground in the north 782; Bulk comb honey, how to prevent leakage when shipped in friction-top caps 598; Bulk comb honey in Colorado 281; Bulk comb honey in the north 280, 281, 689; Bulk comb honey not a competitor of comb honey 356; Bulk comb honey, not chunk honey 372; Bulk comb honey, practical only in the south 716; Bulk comb honey, real price of 680; Bulk comb honey, Scholl on 698; Bulk comb honey, Scholl on price of 580; Bulk comb honey, to prevent from candying 698; Bulk comb honey v. comb honey production 246; Bulk comb vs. chunk honey 441; Bulk comb v. section honey, Scholl on 39; Bulk comb honey v. section honey, Wilder on 12; Burr-combs bad about pinching bees 748; Burr-combs, objections to 612, 715; Bush, quick-growing for shade 621; Business man's apiary in Texas 724; Butter-scotch made of honey 270; Byer, J. L. 70.

Cages, easy way of putting bees in 738; Caging bees, new plan for 59; California, adulteration in 749; California, another failure in 378; California as a bee country 718; California bee-keeping compared to that in the east 681; California convention, report of 262; California department attracting bee-keepers to that state 613; California, different bee-keepers in, visited 325, 522, 681; California, disease in 453; California, disease law in a failure 767; California, pleasing prospects in 326; California, short crop in Imperial Valley 653; Canada, condition of bees in spring 281; Canada, prospects for this season 339; Candied extracted honey for winter food 92; Candied honey, see Granulated honey; Candy, can bees be wintered on alone? 771; Candy factories, bees in 781; Candy, increased use of in United States 4; Can-filler, Evans automatic 489; Canning fruit with honey 463; Cans, importance of using new ones 310; Can, 60-lb. too large for retailing 695; Cans, who pays cost of? 392; Capping-melter did not work satisfactorily 716; Capping-melter, improved 185; Capping-melter, new way of using 163; Capping-melter, Orton's 591; Capping-melters, further improvements in 555; Cappings, washing honey from 532; Carbollic acid for routing swarms in hollow trees 544; Carbollic acid in spraying fruit-trees 223; Carbollic acid in spraying mixtures 37; Carbollic acid not used for spraying 127; Carbollic svrup for curing foul brood 417; Carbon bisulphide, amount needed for fumigating 544; Car, how to load bees in, Weaver on 726; Carniolans, color of 751; Carniolans more adapted for a

specialist bee-keeper 751; Carrying hive into cellar, Holtermann's method 753; Carrying hives, Dr. Miller's method 780; Carrying honey, New Mexico way 790; Cartons for candied honey 384; Cascara as a honey-plant 26; Cases for 60-lb. cans too light 512; Cave, will bees do well in? 566; Celery industry of Manatee Co., Florida 286; Cellar above ground 565; Cellar adjoining furnace for bees 668; Cellar, advantage in taking bees in early 714; Cellar, cost of putting colonies in 36; Cellar, cushion not necessary in 748; Cellar, Holtermann's method of carrying hives into 753; Cellar, ideal conditions when bees are removed from 244; Cellar, ideal, that does not give good results 735; Cellar, is it necessary to have temperature uniform in? 715; Cellar, moving bees before placing in 702; Cellar, not needed in California 613; Cellar, removing hives from without the bottom-boards 702; Cellar, screening the hives in 701, 770; Cellar, sliding hives into 621; Cellar, sub-earth ventilators for 517; Cellar, what is the matter with? 801; Cellar, what kind of cover should be used over hives in? 772; Cellar, when Dr. Miller removes bees from 208; Cellar, when to put the bees in 648; Cellar, when to take bees from 194; Cell, how soon may one be given after queen is removed 769; Cells hatching in nuclei or nursery cages 496; Cells, how built in nature 511; Cells made larger to get larger bees 730; Cells vs. virgins 339, 404, 566; Cell wall thickened in old combs 4; Cement hive-stands 208; Census does not show bee-keeping fairly 246, 512; Census, poor year for 308; Chaff, hive with loose bottom 769; Chaff hives used on the Doolittle plan 128; Chaff-hive walls too thin 72; Charcoal, honey can not be filtered through 59; Chicago-Northwestern convention, Holtermann's report of 45; Chickens and bees in the same building 186; Chickens eat drones only 328, 391, 529, 655; Chickens eating bees 670, 681; Chickens, how to catch 663; Chickens that ate worker bees 598; Chilling bees at the entrance 128; Chittam an important honey-plant 420; Chunk honey, see bulk comb-honey; Churches hold colonies of bees in the wall 749; City bee-keeping 485; City lot, seven hundred dollars profit from 670; Cleaning extracting-combs 427, 446; Cloth to reinforce foundation 460; Clover blossomed long before it yielded honey 404; Clover-flow cut short in Marengo 476; Clover killed by drouth 511; Clover, prospects for 208; Cluster close to the entrance 68; Clustering out in fall, explanation of 670; Clustering out, should it be allowed? 440; Clustering space above top-bars, doing away with 737; Cluster, why formed toward entrance 27; Cocoons spun by larvae 786; Cold kills bees 68; Cold snap in Colorado during honey-flow 615; Colonies must be kept strong for the honey-flow 738; Colonies, size of before honey-flow 333; Colonies strong too early 479; Colonies, two in a hive 236; Colony in open air 349; Colony long queenless, what to do with 646; Colony proper strength of in spring 339, 404; Colorado convention, Foster's report 6; Colorado, honey prospects in 478; Color, effect of on bees 14, 387, 409; Color of bees, variation in 636; Color of old honey darkened 101; Comb and extracted honey in the same super 347; Comb building under bottom-bars, how to prevent 440; Comb honey breaking out of sections 209, 750; Comb honey, Foster on freight rates 69; Comb honey from nectar to market, House on 699; Comb honey in cartons v. bulk honey 372; Comb honey, individual service 130; Comb honey in small packages 245; Comb honey kept in attic 612; Comb honey lie, united effort needed to put down 767; Comb honey prices good 682; Comb honey produced at side of brood-nest 423; Comb honey shipped without glass 209; Comb honey should be stored up stairs 597; Comb honey super, Howell's improved 735; Comb honey, unsealed cells leaking 615; Comb honey, when should it be removed? 566, 635; Comb honey without separators 518; Comb honey without separators, Simmins on 324; Combs as feeders, 198, 406, 497, 565; Combs built perfect without splints 47; Combs, characteristics of normal 453;

Combs cleaned from foul brood, Stewart on 415, 445; Combs diseased with foul brood can not be made safe to use again 646; Combs, how often should they be renewed? 751; Combs melting when entrance was contracted 426; Combs, new, best honey comes from 667; Combs of honey reserved for use in spring 612; Combs old, bees have preference for 646, 781; Combs, old, diameter of cells left in 4; Combs, old, light honey produced in 591; Combs on which bees have died used again 270, 769; Combs, wisdom of keeping the same order of 407; Comb v. Extracted honey production 225; Comb, worker, thickness of 646; Commission men, frauds among 547; Community hive, Phillips on 762; Concrete floor for bee-yard 597; Concrete for hive-covers 597; Concrete slabs for hive foundation 379; Contracting brood-chambers when putting on supers 208; Contraction in production of honey 336; Co-operation among bee-keepers, Raufhuss on 699; Corrugated-paper shipping cases, see shipping cases; Cotton as a honey-plant 21, 162; Cotton furnished honey in spite of long drouth 734; Cotton, honey from leaves of 373; Cotton honey of good quality 766; Cotton taking place of alfalfa in California 653, 756; Cover, Foster's ventilated 583; Covers of both wood and concrete 597; Cow pea, honey from 326; Cross bees, Doolittle on 444; Cuba, conditions brighter in 667; Cushion not necessary over bees in cellar 748; Cushions, absorbing vs. sealed covers, see Absorbing Cushions; Cutter for transferring both the cell and larva 765.

Damages claimed from foul brood 596; Dampening sections, Dr. Miller's plan for 308; Dampening sections, Foster's method of 293; Dandelion and heartease becoming valuable 646; Danzenbaker frames spaced wide for extracting 92; Danzenbaker hives, transferring into 327; Decoy hives in trees 405; Demonstrations with bees, pointers on 702; Demonstrator, bee, wearing only a bathing suit 759; Demonstrator of bees as interesting as a snake charmer 738; Disease among Catherine Beattie's bees 670; Disease attacks adult bees 248; Diseased colony does not work in super 714; Disease, foul brood, see Foul brood; Disease in California 411, 453, 613; Disease law in California a failure 767; Disease of Catherine Beattie's bees due to confinement 631; Disease of Catherine Beattie's bees cured by new queen 670; Disease, puzzling set of symptoms of 516; Disease situation in Canada 229; Disease, Stewart on 415, 445; Disease, Stewart's plan tested 759; Disease, Stewart's plan vs. Alexander's 476; Disease, strong colonies of Italians or Carniolans necessary in curing 683; Diseases of bees, Beattie on 377; Disinfecting alighting-boards 308; Disinfecting foul-broody hives on large scale 77; Disinfecting hives and frames 244, 327; Divisible hives all right for comb honey 262; Divisible hives bound to become standard 441; Divisible hives described in old book 28; Divisible hives, disease in 328; Divisible hives, weak points in 235; Division-boards made of tin 466; Double bottom-board, description of 693; Doughnuts made of honey 124; Dovetailed corner all right in Marengo 371; Dovetailed hive-corner, to make 355; Drifting, Holtermann on 196; Drifting of bees removed from cellar 208; Drone-cells, workers reared in 440; Drone-rearing colony, how to maintain 533; Drones, are they ever wintered over? 272; Drones, early 766; Drones eaten by chicken 328, 391, 529, 655; Drones from laying workers, can they fertilize queens? 769; Drones, how Doolittle secures a supply of 211; Drones, Simmins on selection of 582; Drones, why are large numbers reared, Bullamore on 788; Drones, why many are reared by Caucasians 90; Drouth did not hinder yield of honey from cotton 734; Drouth killed clover 511; Drouth, worst known in Marengo 578; Dwarf bees the result of very old comb 174; Dysentery, disease resembling 516; Dysentery stains inside of hive 164; Dzierzon theory, it is all wrong 715.

Ears, do bees have such organs? 711; Eggs, do bees carry them? 91, 108, 272, 412, 427, 481, 520; Eggs in queen-cells the only ones in hive 636; Eggs, number of laid by queen 476; Eggs

that did not hatch 634; Egyptian bee-keeping, ancient 383; Electricity for imbedding foundation 668; End-bars device for holding while nailing 625; England, some apiaries in 415; English and Canadian systems compared 210; Entrance, Scholl's method of varying size of 593; Entrances in winter, size of 209, 280, 254, 309, 356; Entrances, keeping them free from snow 802; Entrances, large vs. small in the south 457; Entrances, open, in cellar 338; Entrances too close together in community hives produce bad results 780; Entrance, upper 769; Entrance, ventilation at to prevent swarming 464; European foul brood, Alexander plan for 68, 80, 125, 141, 143, 490, 545, 551; European foul brood, Bender on 42; European foul brood, cause of trouble 428; European foul brood, discussion on 141-147; European foul brood, Dr. Miller gives more facts on 8; European foul brood, Dr. Miller on 8, 68, 143, 649, 753; European foul brood, Italians immune to 533; European foul brood, sign of 511; European foul brood varies in virulence 38; European foul brood, Williams on 85, 119; European foul brood, will it reappear at Dr. Miller's 9; European not so dangerous as American foul brood 748; Evans automatic can-filler 489; Excluder as used by Doolittle 300; Excluder not needed on eight-frame hive 308; Excluders do not interfere with the storing of honey 22; Excluders, no reason for not using 525; Excluders with bee-spaces running crosswise 428; Exhibiting bees at fairs 458; Exhibitions, value of to bee-keepers 619; Express companies paid two claims 716; Express rates exorbitant 532; Express shipments more liable to breakage 547; Extracted-honey production, Byer on 698; Extracted honey, tendency toward in Canada 683; Extracted vs. comb honey, Doolittle on 408; Extracting-combs, number of sets needed per colony 484, 563; Extracting-combs to clean 427, 446, 683; Extracting during a honey-flow 342, 579; Extracting during flow to secure a large yield 579; Extracting-frames in comb-honey supers 533; Extracting from all yards at one place 162; Extracting by hand, loss of honey from 579; Extracting by hand and by power 579; Extracting honey in a tent 624; Extracting, how to tell when honey is too thin for 660; Extracting-supers over excluders 195; Extracting, time for 71; Extracting without an extractor 496; Extractor, how large needed for forty-colony apiary 772; Extractor, is one needed for 23 colonies? 139; Extractor, reversible, not speedy 716; Extractors, improvements in suggested by Metcalfe 515.

Fair, New England, Gates on 653; Fairs, exhibiting bees at 458; Fall flow, strong colonies needed for 617, 683; Fan for cooling extracting-room 556; Fasting method of introducing queens 313; Faucet, self-measuring for honey tank 694; Feeder made from two-quart Mason jar 725; Feeder, new way of making 172; Feeders, percolating, Simmons on 550; Feeders, percolator Holtermann on 614; Feeding back honey from cappings 532; Feeding between fruit-bloom and clover, Crane on 700; Feeding between fruit-bloom and clover, Green on 802; Feeding candled honey 4, 309, 512; Feeding combs of honey in early spring 236; Feeding, expensive, by Holtermann 407; Feeding for stimulating in spring 199, 353, 748; Feeding for stimulating introduces foul brood 546; Feeding for stimulative purposes does not pay 651; Feeding in spring usually detrimental 248; Feeding late advocated 512; Feeding late must be done with a pepper-box feeder 781; Feeding on percolating plan in Miller feeder 646; Feeding, out of door plan recommended 545; Feeding syrup in combs 198, 406, 497, 565; Feeding thick syrup late, advantages of 281; Fermenting honey 636; Fertile workers, see laying workers; Fertilization of blossoms by bees 251; Fertilization of fruit aided by bees 4; Fertilization of fruit-trees, colonies needed for 235; Fertilizer for buckwheat 152; Fertilizing, should bees be scattered for 511; Field bees unloading in brood-chamber 4; Fielders, number of in normal colony 136; Field meeting of Mass. bee-keepers 690; Field pea, some honey secured from 328; Flat wrappers of

A B C & X Y Z of Bee Culture, new edition 401; Absorbents vs. sealed covers 206, 207; Adulterators being brought to time 170; Alexander cure, was it wise to publish? 509; Alexander foul-brood cure, old 778; Alexander plan of curing European foul brood 1, 65, 541, 778; Alfalfa honey, to keep from granulating 134; American and European foul brood names 370, 507; American Apple Orchard by Waugh 242; Anatomy of the bee by Snodgrass 437; Apiaries and line fences 206; Apiary, locating 205; Apis nosema 368; Automatic can-fillers 438, 575; Automobile for apiary work 97, 243.

Baby nuclei for queen-rearing 279; Bacillus larvae and bacillus alvei recognized by an English authority 542; Back-lotter bee-keeping 778; Banats 747; Bee books, new, in press of Gleanings 643; Bee company, 50,000-colony 402; Bee disease not a disease 368; Bee-house, double-walled 98; Bee-keepers, legal rights 277; Bee-keeping for beginners 778; Bee-keeping on a large scale 241; Bees and fruit 577, 643; Bees and neighbors 34; Bees as fertilizers of cranberry blossoms 643; Bees distinguishing colors 777; Bees in candy factories 644; Bees in clamps in clay soil 678; Bees, interstate shipments 1; Bees killed by poison 335; Bees killed by spraying-liquids 278; Bees more hostile to black than white 711; Bees moved short distances without going back 645; Bees, semi-hibernators 35; Beet-tent 367; Bee-trees contain foul brood 575; Bloating among cattle 97; Books, new, in press of gleanings 643; Brush automobile 243; Bulk honey 33; Bureau of Entomology 2; Bureau of Entomology bulletins 437; Büttele-Reepen's book 66; Byer, J. L. our new Canadian editor 778.

California crop light 241; California, southern, not a bee paradise 610; Candy factories and bees 644; Candying of honey, see granulation; Candy with meal in it 98, 99, 134; Carboic acid in spraying mixtures 134; Cattle, bloating of by clover 97; Cellar wintering, points to be observed 779; Cells vs. just hatched virgins 336; Characteristics of the races 747; Clamps for wintering in clay soil 678; Cloth for supporting foundation 133; Clover and its relation to heavy snows 97, 170; Clovers cause bloating in cattle 97; Clover very promising 335; Clusters, contraction of in winter 35; Coddling moth and its ravages 743; Cold weather before the honey-flow 367; College expenses paid by bees 134; Collier's

Weekly and the comb-honey canard 745; Color sense of the honey-bee 777; Comb-honey canard in Collier's Weekly 745; Combs honey canard refuted 367; Comb honey, candied, what to do with 279; Comb honey candying, how to prevent 278; Comb honey giving way to extracted 542, 678; Comb honey, high price of 678; Comb honey, how to ship 644, 777; Comb honey unsalable, what to do with 677; Combs, arrangement of for winter-nest 677; Combs, not necessary to melt up on European foul brood 611; Combs, rendering into wax 67; Convention, National 66; Corporation of 50,000 colonies 402; Corrugated paper for shipping-cases 169, 745; Cranberries fertilized by bees 643; Crop-reports 509, 510, 542; Crop report, scheme for 402; Cushion, see absorbents; Cyprians 747.

Disease, nomenclature of 370, 507; Diseased brood to the Bureau of Entomology 473; Disease, Malden's paper on 542; Disease, to prevent in California 610; Doolittle on baby nuclei 279; Doolittle on bees and fruit 577; Doughnuts, honey 34; Drouth and honey-flow 242; Dysentery instead of nosema apis 368.

Editor of Gleanings foul-brood inspecting 508; Editor through Canada 609; Edwards, D. M. death of 746; Entomology, Bureau of 2, 437; Entrances, size of 207; Entrances, size of for winter 711; Entrances closed by dead bees 133; European foul brood, S. D. House on 611; European foul brood, to cure 1, 65, 611; Excluders, wrong and right side up 34; Extracted honey automatically cut off 438; Extracted honey, clarifying 402; Extracted, tendency toward rather than comb 543, 678; Extracting-combs, wet, robbed out 541; Extracting honey, modern methods of 402, 473; Extracting, Metcalfe's methods 777; Extracting-room, keeping cool with fan 473; Extractor, honey 98; Extractors, light non-removable 541.

Fakes and fakirs 241; Fan to keep extracting-room cool 473; Feeders, percolators 541; Feeding, injudicious 368; Feeding late for winter 643; Feeding late or early 207; Ferguson uncapping-machine 576; Fertilizers, bees as 643; Forest fires and hive lumber 542; Foster, married 609; Four-brood, Alexander cure for 1, 65, 541, 778; Foul-brood bill, New Jersey 305; Foul-brood bill, Ohio 135, 171; Foul-brood cures by shaking or brushing on foundation 543; Foul-brood, eliminating the old-fashioned bee-keepers 508;

Foul-brood, European 1, 65, 611; Foul-brood, European, can combs be used again 611; Foul-brood in bee-trees 575; Foul-brood in Indiana 369; Foul-brood inspection by the editor 508; Foul-brood inspection as carried on in different states 369; Foul-brood legislation in Kentucky 2, 473, 609; Foul-brood legislation in Massachusetts 241; Foul-brood names, European and American 370, 507; Foul-brood, new methods of cure exploited 508; Foul-brood samples, to Bureau of Entomology 473; Foul-brood spreading in California 610; Foul-brood treating in late fall or winter 644; Foul-broody combs, shaking or brushing 33; Foul-broody honey, using again 67; Foundation, early invention of 98; Foundation, new or old 277, 335; Foundation, Poppleton's method of staying 66; Foundation stayed by cloth or paper 133; Freight rates, advancing on comb honey 746; Fruit, bees and 577, 643; Fruit culture and spraying 242, 278; Fruit-growing and spraying 205; Fruit trees damaged by recent cold 335.

Gleanings cover design 34, 65; Gleanings, early history of 99; Government bulletins 437; Government work 2; Granulating of alfalfa honey 134; Granulation of honey, how to hasten 134, 135; Granulation, prevention of in comb honey 278; Greenhouse, wintering 98.

Hand method of controlling swarms 679; Hand system of swarm control, very old 778; Headache cures and short weights 307, 368; Hibernation, semi, of bees 35, 576; Hive, Langstroth 98; Hive lumber and forest fires 542; Hives, double-walled vs. those packed in paper-cases 745; Hives, 10-frame vs. 8-frame 241, 306, 712; Hives, location of 206; Holtermann retires from editorial staff 778; Honey, American, refused in South Africa 133; Honey, aster, for winter stores 711; Honey cooking receipts 777; Honey, cost in comparison with other foods 33, 65, 170; Honey-crop conditions 401, 575; Honey-crop in Michigan 541; Honey-crop reports 438, 439, 474, 475; Honey crop very light 609, 643; Honey-dew and wintering 170; Honey-dew prevalent in 1909 169; Honey doughnuts 34; Honey from foul-broody hives 67; Honey in bulk 33; Honey much in demand by buyers 609; Honey, prices in comparison with other foods 33, 65, 170; Honey, selling, Hutchinson on 305; House, S. D. on European foul-brood 611; Hutchinson on selling honey 305.

Ideas, new 335; Ignorance of the public on bee matters 575; International Harvester automobile 243; Interstate shipment of bees 1; Introducing, Simmlins's method 778; Italians and Carniolans 747; Italians, Golden 747.

Jumbo hive, change to 254.  
Kentucky foul-brood legislation 2, 473, 609; Knot-weed 144.

Law, model foul-brood 643; Legal rights, bee-keepers 277; Liquefying candied comb honey 278, 279; Lumber, effect of forest fires on prices of 542.

McEvoy method of treatment 543; Malden's paper on bee diseases 542; Manley on wax rendering 337; Meal for brood-rearing in early spring 134; Metcalfe's method of extracting 777; Michigan Association, how it helps its members 576; Michigan State Convention 609; Misbranding 307, 368; Moth, codling 243; Moth worm a disappearing pest 34; Moving bees short distances in the same yard 711, 645; Moving pictures for Gleanings 543.

National Bee-keepers' Association booklet 277; National Convention 66, 677. New Jersey foul-brood bill 395; Nitrogenous food for bees 98, 99, 134; Non-swarmling devices 277; Nomenclature of foul-brood 370, 507; Nuclei for queen-rearing 279.

Ohio Bee-keepers' Association 135; Ohio bee-keepers at Columbus 35; Ohio four-brood law 171, 306, 367, 610; Ohio inspection work 575.

Paint for hives 576; Parcels post 277; Patent medicine fakirs 368; Patents bearing on foundation stretching 133; Pearce's book for farmers 677; Perforated zinc, right and wrong side up 34; Phillips, Dr. E. F. at Medina 367; Phillips's work at the Bureau 2; Poison, bees killed by 355; Pollen, artificial 98, 99, 134; Poppleton on staying foundation 66; Prospects for 1910 277, 278; Power vs. hand-driven extractors 401; Pratt's methods, why some could not succeed with 279; Pure-food law, National 307, 368.

Queen allowed in extracting-supers 508; Queen, Miller's method of finding quickly 192; Queens, wintering more than one in a hive 678.

Races, characteristics of 747; Receipts, honey 777; Reflex machines, Buttel-Reepen 66; Rendering combs into wax 67; Reo automobile 243; Rheumatism and bee-stings 403; Robber-cage, anti 367; Robber traps not a needless appliance 1; Robbing out wet extracting-combs 541; Robbing, secret of prevention 401; Root, A. I. Company's plant, enlargements 643; Root, A. I. early bee-keeping experience 98; Root, A. I. relieving of work 33; Root, A. I. writing for the American Bee Journal 99.

Sage honey, light crop of 169, 241; Sealed covers vs. absorbers 206, 207; Section-box for shipping honey 711; Selling honey to the best advantage 305; Shade for bees 206; Shaking or brushing foul-broody combs 33; Shipments of bees, interstate 1; Shipping-case, cheap 610; Shipping-cases, factory made vs. home made 644, 746; Shipping-cases, reducing number of 712; Shipping cases, uniformity of 713; Shipping-cases with corrugated paper 169, 745; Shipping comb honey, our antiquated methods of 777; Sibbald wax-press 337; Spraying and its relation to fruit 205, 278, 335; Spraying liquids killing bees 278; Spraying poisons, carbolic acid 134; Spring, very early 1910 242; Standardization of hives 306; Standardization of hives and shipping-cases 242, 712; Stewart, Henry cure of 509; Stings and rheumatism 403; Strainer vs. settling tank for extracted honey 402; Supply year great 335; Surface on hibernation 576; Swarm control, Hand system, old 778; Swarming controlled by the Hand method 679; Swarming, how to keep down in extracting-yard 508; Syrup for winter feed 711.

Ten-frame vs. 8-frame hives, see hives 8-frame vs. 10-frame; Tent for bees 367; Townsend bee book 678; Townsend on clarifying honey 402; Trees, foul brood in 575.

Uncapping-machine, Ferguson 576; Uncapping-tank, McIntyre's 403; Uniting, some tricks of the trade in 644; Uniting without bees going back 711.

Virgins vs. cells 336.

Vaugh, F. A. on spraying 242, 278; Wax rendering 337; Weaver's Virgil prophecy 242; White of the Bureau of Entomology vindicated 542; Winter-cases of paper 207; Wintering at Medina and over the country 169, 206, 207; Wintering in clamps in a clay soil 678; Wintering in different parts of the country 205; Wintering indoors, a few tentative propositions 779; winter losses 133, 335; Winter nests, arrangements of comb 677; Winter reading 66; Winter, snug 1.

York of the American Bee Journal married 507.

#### A. I. ROOT'S DEPARTMENT.

Alice Hilbert, death of 165; American Politics, problems in 673; Army of drunkards 639; Automobiles run by mischievous boys 774; Automobiles that cost no more than horse and buggy 674; Aviation meet at Cleveland Centennial 705.

Balloon, meals served on 436; Bermuda grass and stick-tight fleas 605; Blackberry, Northey 333; Black chickens from white

rooster and Plymouth Rock mother 805; Blueberry under cultivation 807; Brakes, emergency 129; Breakfast, going without 398; Brooder, A. I. Root's fireless 62; Brooder, Clough's 204; Brooder, Curtis fireless 471; Brooder, "Lullaby" 131; Brooders, fireless 166, 204; Brooder made from basket 62, 94; Bryan's views on liquor question 640; Buckwheat, Japanese, a protest 436; Buttercups 167; Butter-

cups, another report on 805; Buttercups begin laying 332.

Cactus, thornless 63; Carbolinum as a remedy for vermin 435; Chestnuts, valuable aid to health 803; Chickens, getting rich with 302; Chickens, in Florida 61; Childs, John Lewis, letter from 32; Chufas as good as chestnuts 803; Church moved because too close to saloon 304; Cigarette fiends, none on payroll 64; Cigarettes for minors, law against 394; Cigarettes pushed in China 393; Cigarettes, twenty million in China 361; Cities, fresh air in 739; Conscience clear 130; Consumptives, milk strippings for 168; Cornfield at Medina, results from 807; Cornfields on the way from Florida to Medina 571; Corn story 431; Cosmopolitan, Russell's sermon in 599; Counterfeit money 93; Coveting 93; Cowles, A. F. tract distributor 537; Crossing, protest against haphazard 203; Crushed wheat, home-made 274.

Drugs to make chickens lay 365; Drunkards, army of 639; Drunkards, none on payroll 64; Dry cities, wet mayors for 776; Dry county, no business for grand jury in 366.

Eating to keep well and live long 30; Egg-books, Corning 132; Egg-book, Corning, criticism of 303; Eggs found under the roosts 364; Eggs in the summer, in Florida 204; Eggs shaken by sitting hen 63; Eggs without shells 363; Egg-tester, how to make 239; Electropoise 642; Electropoise, oxydonor, etc., 608; Eucalyptus in Florida 434; Everglades of southern Florida 707.

Fasting to secure perfect health 429; Fasting, Upton Sinclair's plan 330; Feather dusters for raising little chicks 806; Fertilizing truck land in Florida 276; Filter for drinking-water 574; Firebugs burn entire village 601; Fleas, stick-tight 435; Fletcherizing 301; Flight from Chicago to Springfield 675; Florida, discouraging things about 641; Florida in the summer time 433, 537, 572; Flying-machines in Sunday flights 703; Flying-machines in France 641; Flying-machines up to date 472; Flying-machine, Wright Bros.' up to date 602; Food at low cost thirty-five years ago 397; Food, going without 330; Forgetting 773; Fresh air in cities 739; Frost, is there any part of Florida free from 434.

VOL. XXXVIII

JANUARY 1, 1910

NO. 1

## EDITORIAL

By E. R. ROOT.

It takes but a glance at the cover design for this issue to bring to mind the fact that this is truly a wonderful age. It has been a long time since 1810, and with this thought comes the query: What will bee-keeping be like 100 years hence?

### OUR INDEX FOR 1909.

THE voluminous index for the year 1909 gives promise of the extent and character of some of the good things we shall have for 1910. This index was prepared with the greatest of care by our editorial force, and our readers during the winter months will have an opportunity to go over some of the discussions of the past summer, taking them up by topic or otherwise as they may prefer.

### THE ALEXANDER PLAN FOR CURING EUROPEAN (BLACK) FOUL BROOD.

MORE proof is beginning to accumulate to show that, in the case of European or black foul brood, the queen herself, and especially the kind of strain from which she comes, is apparently one source of infection. It would begin to seem that a combination of the McEvoy and the Alexander forms of treatment might be employed to great advantage. In some cases, at least, a modification of the Alexander treatment, killing the queen and requeening in three weeks, is sufficient to effect a cure.

In a matter of such paramount importance as this, GLEANINGS feels that it can not afford just yet to proclaim to the bee-keeping world that the Alexander form, or modified form of it, is going to bring relief. For the present, at least, we are seeking evidence, and wish to have the truth without favor or prejudice.

We shall have an article from a good bee-keeper and an old correspondent in our next issue that seems to favor the findings of Dr. Miller.

### A SNUG WINTER; THE RELATION OF SNOW TO A WHITE-CLOVER FLOW NEXT SUMMER.

We have had about two weeks of severely cold weather, accompanied by a high wind. Mercury has been down as low as 3 or 4 de-

grees above zero, and much of the time about 10 degrees above. The weather is moderating somewhat, and the ground is now (Dec. 25) covered with snow. Dr. Miller reports good sleighing at Marengo, and consulting the newspapers we find that there is considerable snow all over the United States. This is a good omen for clover, for we have always noticed that, when the ground was covered with snow much of the year, if we do not have bad winter-killing and a late spring, we are almost sure to have a good clover crop, and a good yield of nectar during the following summer. An open winter we find, also, is apt to be destructive because of winter-killing. Clovers can stand a hard severe freeze; but an alternate freezing and thawing, with rains, sleet, and snow, tears the clovers, root and branch, resulting in what we call winter-killing. The best condition of all is a deep snow lasting a good part of the winter, and an early spring.

### IMPORTATION AND FEDERAL CONTROL OF INTERSTATE SHIPMENTS IN BEES.

MR. HOLTERMANN, in his department on page 5, in referring to the question of subjecting bees to quarantine before entrance into this country, calls attention to a statement made in England that "The United States Board of Agriculture were most careful in their regulations to prevent the chance of conveying disease into that country." In the first place, there is no "United States Board of Agriculture" that we know any thing about. Undoubtedly the United States Department of Agriculture is meant; but the Department has no authority to make such "regulations" nor to enforce them if it had. The Bureau of Entomology, through its Apicultural Expert, Dr. E. F. Phillips, has suggested that Congress ought to pass a law to control the importation and interstate shipments in bees. Until Congress does take such action the Department of Agriculture is powerless to act. That Uncle Sam will have to exercise some sort of control is generally admitted. At present, minor legislation, such as a United States bee-disease law, will probably be sidetracked to let in something else involving larger interests.

The statement is also made that "foul brood is prevalent in Northern Italy." At the present time there are only very few queens sent from Italy into the United States, and what do come over are in long-distance mailing-cages. On arrival into this country

they are introduced into a nucleus or colony, and tested to determine their grade.

This detention in the yard of a queen-breeder would afford all the quarantine that would be needed to insure safety before sending out to the general trade.

The time will come when we should unitedly ask for a Federal law to control not only the importation of bees into this country, but interstate and territorial shipments of them. The time is not opportune for asking any thing of this kind just yet, but it will come later.

#### ARE ROBBER-TRAPS A NEEDLESS APPLIANCE IN A WELL-REGULATED APIARY?

MR. HOLTERMANN, in his department, page 5, thinks the user of robber-traps ought to be "trapped," or, in other words, he probably means that in a well-conducted apiary there should be no robbing, and therefore no occasion for a device of this kind. Our correspondent is a honey-producer, and possibly and probably is not familiar with the conditions surrounding queen-rearing yards. We have at our home apiary, as we believe, one of the most careful men we ever had; but every now and then his helper will be a little careless, and allow robbing to get started. If a bee once gets a taste of stolen sweets it will be almost sure to begin the business of following up or hanging around baby nuclei, and the sooner it is caught in a trap, the better for those babies. We venture to say that Mr. Holtermann probably has as much difficulty in getting help that will heed instructions about robbing as we do. If he can get a new man who will let no robbing get started he is doing better than we can. While a few robbers in a yard where honey is produced, and colonies are strong, cause no trouble, they are a perpetual nuisance and expense in a queen-rearing yard.

Again, there are other times in an extracting or comb-honey yard where it will be well to put a robber-trap in operation. This is especially true where the bees are located next to a highway. We have demonstrated to our satisfaction that robbers generally come from only one or two colonies. The old fellows in these hives teach the younger ones their bad tricks. Trap them once, and the power of a bad example is eliminated, and one can work among his bees with some degree of comfort.

#### FOUL-BROOD LEGISLATION FOR KENTUCKY.

THE bee-keepers of Kentucky are making a strenuous effort to secure some form of foul-brood legislation. Those who know the situation best think it would be impracticable to secure a State-wide foul-brood law, because the legislature would not appropriate the funds sufficient to pay a State-wide inspector, including his necessary expenses. They have, therefore, drawn up a bill that is based somewhat on the county law in Ohio.

This bill, in brief, provides that, when a petition is presented to the county judge in

any county in the State of Kentucky, signed by three or more bee-keepers, stating that certain apiaries within the county are affected with disease, said county judge shall appoint a bee-inspector. Said inspector shall inspect all colonies of bees, hives, and implements, and shall notify the owner if disease is found, and how to cure the same; that if the owner fails or refuses to apply the treatment, the inspector may order their destruction as a nuisance. There are other provisions that usually go with the ordinary foul-brood bill.

The funds for this measure are to be provided by a special tax of five cents for each colony owned in the State. The amount so collected shall constitute a special fund to be disposed of in the payment of the salary and actual expenses of the bee-inspector. It is also provided that said fund can be used in no other way.

This is, in substance, the form of the Ohio law, with two exceptions—1. Our statute imposes only a one-cent tax; and, second, if the funds so collected are not called for within three years they are to revert to the general fund. These two provisions make our Ohio law a practical dead letter. In the first place, the one-cent tax does not provide sufficient funds to pay an inspector, in the average county, for time and expenses to do his work in a satisfactory manner. In the second place, what little moneys do accumulate are very apt, by the three-year provision, to go into the general fund. About the time that foul brood is discovered, there are no funds available unless the disease breaks out before the expiration of the three-year limit; and even then, as we have explained, the funds are insufficient.

The bill that our Kentucky friends have drawn seeks to eliminate these two bad features. Drs. E. E. Corliss, of Brooksville, Ky., and M. A. Aulick, of Johnsville, Ky., would like to get in touch with all those who would co-operate in getting this bill enacted into law. Our Kentucky subscribers are requested to communicate with them at once.

#### THE WORK OF THE BUREAU OF ENTOMOLOGY ON BEE DISEASES FOR 1909.

IT may be of interest for us to present to our readers a brief account of the work of the Bureau of Entomology of the United States Department of Agriculture on bee diseases for the year 1909. This work was begun by Dr. E. F. Phillips as soon as he took charge of the bee-keeping work for the Bureau. He was fortunate in securing the services of Dr. G. F. White as bacteriologist. Dr. White is doubtless the best-trained and most experienced man at work on this important line of investigation, and he has already obtained results which have baffled bacteriologists for many years. The year just closed has been by far the heaviest in the history of this work.

In 1908 Dr. White established the cause of American foul brood to be *Bacillus larvæ*, and since that time he has been engaged in

a more detailed study of this bacillus for the purpose of applying knowledge of this germ to practical treatment.\* He has also been at work on European foul brood, or "black brood," as it is sometimes called. It will be remembered by many of our readers that, at the Detroit meeting of the National Bee-keepers' Association, Dr. White mentioned another bacillus which he suspected might prove to be the cause of this disorder. This has not been fully proven yet.

During the summer of 1909 the Bureau asked for samples of diseased brood from all parts of the United States through the bee journals. Thousands of circulars were also sent out to correspondents, asking for samples where diseases existed. As a result, over 600 samples of brood were examined bacteriologically, bringing the total number which are recorded to more than 1000. At the Sioux City meeting of the National Bee-keepers' Association, Dr. Phillips showed two maps of the United States, giving the distribution of American foul brood and European foul brood as shown by these samples. These indicated that the two diseases are much more widespread than is usually supposed, and fully justify the position of the Bureau that there is no more important work to be done for American bee-keepers than an investigation of brood diseases. This information concerning the distribution of diseases is being used to send circulars to bee-keepers in infected regions as far as the limited office force will permit, but is of special value for use before legislatures which are being asked to pass foul-brood laws. We understand that the Bureau does not expect to publish this material, at least for another season, in order to make it more nearly complete; but we are sure that any committees which are to present foul-brood bills to their legislatures this year can obtain the available data for their own States by writing to the Bureau.

It is difficult for bee-keepers not trained in bacteriological work to reconcile the conflicting statements of various writers on this subject, or to understand what claims are fully proven. To help clear up this state of affairs Drs. White and Phillips have been at work on a paper in which all the important papers on the causes of bee diseases are reviewed and analyzed, and the claims examined in the light of our present knowledge of these subjects. We understand that this paper is to be completed within a short time, and we hope that it will clear up the present unfortunate confusion.

The bee-keepers of Massachusetts, Pennsylvania, New Jersey, Maryland, Kentucky, Alabama, Illinois, and Oregon are anxious to have foul-brood laws passed, and, as far as possible, in all these cases the Department has aided the bee-keepers in their efforts. In several cases the proposed bills have been partially or entirely drafted by the Bureau.

\* There is some reason in support of the belief that this is what is called *Bacillus Brandenburgiensis*, or *Bacillus Burri*, in Europe. See GLEANINGS, page 684, July 1, 1908.

In asking for such laws the maps showing the spread of the two diseases are of much value, and this information is always given by the Bureau in such cases.

We understand that the Bureau makes it a rule not to write letters to State legislators urging them to pass such bills; and this is perhaps as well, for there might be a feeling on the part of some of these men that the federal Department was trying to dictate what they should do. If the Department furnished all the information which it has at hand to the committee of bee-keepers who are urging such bills, no more can be asked.

It will not do, however, for bee-keepers to rely entirely on foul-brood laws to control diseases. An educational campaign to inform the thousands of bee-keepers over the country is badly needed. The Bureau of Entomology is trying to do its share in this work. When a sample of diseased brood is received, a request is sent for names of other bee-keepers near at hand, and they are also sent a circular on brood diseases. Over 10,000 postmasters were also requested to send in the names of bee-keepers in their vicinities during the summer of 1909, and, as far as possible, circulars were sent to the persons whose names were received. The present appropriation of the Bureau for bee culture will not permit of the hiring of an office force large enough to carry on this work very extensively, but the force is used in this way as far as possible.

In the matter of treatment, the Bureau, we are advised, has not seen fit to change its recommendation of the shaking treatment. Experiments on the effects of various disinfectants on *Bacillus larvae* have been performed, and the effects of various drugs in syrup fed to diseased colonies have been studied. The results of some of these experiments are, we understand, to be published this winter. So far the results have not shown that the drug treatments, so much advocated in Europe, are of any value in practical work.

This result will not be a surprise to American bee-keepers. In a paper read before the National Bee-keepers' Association at Sioux City, Dr. Phillips outlined what is now known and what is not known about the treatment of bee diseases. He pointed out the necessity of a thorough knowledge of the causes of the brood diseases before any great advance can be made in treatment. This is, perhaps, a point which many do not realize; but it is evident that experiments based on such knowledge will give better results than the haphazard recommendations on drug treatments which have so often been made without a basis of facts.

Dr. Phillips announced at Sioux City that, during the season of 1910, the Bureau expects to continue the work on the distribution of the two diseases on a still larger scale. We hope that our readers will co-operate by sending in samples when the time comes to aid in this work which will prove so important to our industry. Let us see if we can not swamp the bacteriologist.

## STRAY STRAWS

BY DR. C. C. MILLER

REFERRING to last item, p. 786, I think the Dadants practice feeding candied honey, smearing it over the top-bars of brood-chamber.

BEFORE 1861 I suffered severely with rheumatism, and since then have had none. I began keeping bees in 1861. I don't know whether there is any relation between the two facts.

HUBER, I have a Quaker mill like yours, and am miller-in-chief to the Miller family. It's great to grind your own wheat, have all of the wheat in the flour, and know just what you're eating. And the gems from that whole-wheat flour! Yum! yum!

J. E. CRANE, it's true, as you say, p. 758, that bees often fill a center bait before strong enough to do much more; but another fact of more importance to me is that that prompter beginning in the center may make the difference between swarming and not swarming.

A MISTAKE is made, p. 727, in saying that hives 10 feet apart in the row and rows 10 feet apart makes hexagons. It makes squares. Put hives 10 feet apart, in the row, and rows 8 feet 8 inches apart, and you will have hexagons, the center of each hive being just 10 feet from the center of each of the surrounding 6 hives. If you put a pair of hives instead of each single hive, you will double the number of hives on the same ground, and be just as safe from bees entering wrong hives.

PRECONSTRUCTED queen-cells are the kind the bees prepare for a prime swarm, and I supposed the only kind. Now comes Adrian Getaz, a careful observer, who says, *American Bee Journal*, 367, that, after having destroyed queen-cells in a colony for two or three weeks, he found some whose bases showed that they were post-constructed, notwithstanding the presence of a laying queen. This, however, was not an entirely normal case of preparation for a prime swarm, as the swarming fever had been intensified by the destroying of previous queen-cells.

J. L. BYER, you seem to be somewhat off in your ideas, p. 780, of what I've been doing. I haven't abandoned feeding thin syrup in the fall, for I never did it. All that I ever did of that was experimentally on a small scale fairly early. Neither would I feed late any thing so thin as two-to-one. I've fed barrels of sugar for winter, but always two and one-half to one, and I wouldn't risk feeding it without acid. I don't know from experience about the two-to-one. No, at present I'm "not mixing honey with the feed." Just now I don't recall ever mixing an ounce of honey that way.

THAT BEES aid in the fertilization of fruits is, of course, well known. That they aid fruits to resist frost is new to me. But that

is just what was claimed in a conversazione, *British Bee Journal*, 413, and with the explanation given it looks reasonable. It is well known that a blossom remains fresh a considerable time awaiting fertilization, and then promptly dries up. Well, during that "awaiting" time the stigma is tender, easily affected by frost; but when dried up the little fruit is resistant. So with plenty of bees there is less danger from frost. [This looks reasonable and we believe it is true.—ED.]

NONE OF MY funeral whether field bees unload in supers or brood-chamber; but it's hardly proven, p. 763, that it's always in supers. That "suppose" 15 pounds a day coming in, and all cells already filled, might be answered by the question, "Does that happen?" At any rate, when honey comes in 12 pounds a day you can always shake thin honey out of the brood-combs by the pound. And there's no need for 12 pounds in the brood-chamber, for some of it could be carried up soon after being brought in. If field-bees go straight to the supers it seems 'hey might take their pollen there too, instead of dumping it in the brood-chamber.

"THE CANDY-BILL of Uncle Sam is \$130,000,000 a year," says the *Baltimore News*. "It is said by experts that the enormous increase in the use of candy is the direct outcome of a corresponding decrease in the use of alcohol. Alcohol destroys the taste for sweets, and correspondingly the heavy candy-eater is not likely to be the person who has a strong liking for whisky, beer, or wine. In the last few years the admitted gain of sobriety among all classes of people has had the effect of adding to the business of the candy-maker by leaps and bounds." All of which is good—very good. Now let the word go out that it would be still better if honey should replace three-fourths of the candy.

LOUIS SCHOLL, p. 757, I don't want to get "a good swat" along with the editor, and so I'd like to come to an understanding. It's a matter of serious practical importance. The belief of some is that the diameter of a cell is constantly lessened by the addition of cocoons to the side-walls, and so no comb more than five years old should be used. I believe that a comb may be used for 50 years or more. There is a constant thickening of the midrib, and a constant deepening of the cell to compensate for it, so that the diameter of the cell always remains sufficient for a full-sized bee. Of course there may be such a thing as such close spacing or such a thick midrib that the depth of the cell is too little for a full-sized bee. But I don't believe it ever happened that a cell of full depth was made too narrow by cocoons for good use. Your bees were dwarfs, not because of the diameter, but the depth of the cells. Neither the editor nor I thought the bees could spread the combs; but we thought the bees could spread the combs; but we thought you were equal to the task, and that if you would do so you would get bees of full size. By the way, that ½-inch midrib must be about 100 years old.

## NOTES FROM CANADA

By R. F. HOLTERMANN.

### QUEENS FROM EGGS.

Page 490, GLEANINGS, I believe you are right, Dr. Miller. When a colony has a queen the bees rear queens for swarming or for superseding from the egg.

### SOUND REASONING.

F. P. Adams, at the recent Ontario convention, stated that artificial swarm control and artificial stimulation should go hand in hand with queen-rearing. He asked where queens would come from when swarming stopped. I share the view expressed by Mr. Gill, in the *Bee-keepers' Review*, page 373, "extensive bee-keepers can't afford to rear many queens," for I have largely bought them.

### ROBBER-TRAPS.

Mr. D. M. Macdonald, in the *British Bee Journal*, page 388, in commenting on these contrivances, pities the poor innocent bees that get trapped with the marauders. In commenting on this, D. G. Taylor, page 397, states, "I think the sympathy is entirely wasted, as the bees which enter a robber-trap, which generally takes the form of a hive, are bees that have the tendency to become robbers." No doubt the bees "have the tendency to become robbers"—*all bees have that tendency*, and therefore such a trap is a folly which I have never heard of in Canada or the United States. The fault lies with the bee-keeper. Trap him. [See editorials.]

### A NEW SITUATION IN CANADA.

At Welland there is a smelter for reducing silver ore from cobalt. In that section the bees have been almost wiped out. Some have lost all; others less. An average report is 6 left out of 45. Some attribute it to the smelter, others to large hornets which have been seen fighting bees at the entrance of the hive. Here is a problem for the government apiarist. The president of the Ontario Bee-keepers' Association, at the recent convention, stated several times that the government had given all that the association asked for. Does our faith fall short of what we might get? Let us ask for first-class equipment at the Ontario Agricultural College, and we shall likely get it.

### BEEES FERTILIZE BUCKWHEAT BLOSSOMS.

During my visit to the Ontario Government Jordan Harbour Fruit Station I noticed a patch of buckwheat, partly enclosed to bar access by the bees and other insects. I at once judged that another long-hoped-for wish that the Ontario Government would carry on investigations in the fertilization of blossoms by bees was beginning to take shape. No doubt the station's first report will be to the Minister of Agriculture, the Hon. J. S. Duff; yet that did not prevent me from adjusting my eye to a small opening

available, and finding that the uncovered buckwheat had at least one third more buckwheat seeds than the covered. The horticultural official at my side, in response to my quick verdict, confirmed my opinion.

### SHALL BEES BE SUBJECTED TO QUARANTINE IN ENGLAND?

In the *British Bee Journal*, page 433, Mr. Reed, at the British Bee-keepers' Association conversazione, stated that foul brood "was so prevalent in Northern Italy that bee-keepers took no notice of it." Then follows a discussion as to the advisability of stopping the importation of queens from this country, subjecting the bees to quarantine. As Mr. Reed states that, with foul brood in the hive, the bees were able to put up with it (the disease) and live and produce honey, I should say if this be true by all means get these bees; but I fancy there is a mistake somewhere. Mr. Reed also states, on the same page, "The United States Board of Agriculture were most careful in their regulations to prevent the chance of conveying disease into that country." If there are such regulations, will the editor of GLEANINGS kindly let us know what they are? I know of none. There is sometimes a difficulty in getting reliable information, especially from a distance. [See editorials.]

The Isle of Wight bee disease appears to have practically wiped out bee-keeping on that island.

### THE PLACE FOR EMPTY SUPERS.

On page 490 Dr. Miller says that, when he puts empty section-supers under a partly filled one in a waning flow, the bees keep on with the super above and leave the empty super untouched. Yes, they may even complete a partially filled section and not touch the neighboring one. This is particularly true when separators are used. Whether it be a comb-honey super or an extracting-super with foundation that is put between the brood-chamber and the super already in use, I find that, with a moderate honey-flow, the tendency is to take no more honey through this empty super than necessary, and, therefore, to crowd more honey into the brood-chamber at the expense of room for brood-rearing. Now, when I add extracting-supers, and can spare the time, I take some of the nearly filled frames from the super already on the hive, put in their place empty combs, and place the new super on top with the combs which have been in use in the place formerly occupied with empties. I also take care to put the empties in the top story above the empties in the lower. This establishes an old or already accepted connection between the upper and lower story, and it makes less of a break in the interior of the hive; and I prefer it very much to leaving all new comb in one super, either next to the brood-chamber or on top. Where more than the number of supers mentioned above are in use I seek to place the frames nearest full in the top super or supers.

## BEE-KEEPING AMONG THE ROCKIES.

BY WESLEY FOSTER, BOULDER, COL.

### SAWED VS. SPLIT OR SLICED SEPARATORS.

The scalloped wood separator is subject to hard usage in comparison to its strength. The scalloped edges break off very easily, and great care must be used in wedging up supers, removing honey from them, and in cleaning the separators. The most breakage comes in scraping off wax and propolis. A wood separator, to be of service, should be sawed and not split or sliced; it should be free from knots and decayed wood, and thick enough so that there will be about fourteen to the inch. Some run as high as eighteen; but this is too thin, and the scallops will break off almost of their own volition. A good time to compare the merits of a sawed and a split separator is after a lot of them have been wet. The sawed separators come back into shape fairly well, while the split separator will remain warped, and, if bent into shape, will likely break.

I do not agree with the ideas of Mr. Trickey, as given on pages 722 and 723, Dec. 1, that comb-honey cases are made too strong. The single-tier wood case is not protection enough for the honey. The freight-handlers have so many goods to move that often no time can be had to move goods slowly. This is not as we would wish; but we shall have to do the best possible, and continue to fight for more careful handling of fragile goods. The railroads out this way have claims for breakage on a very large percentage of the local shipments of comb honey. The breakage is caused by careless freight-handlers, packing in cars with heavy goods, and by hard bumping of cars when switching. The rate on comb honey will no doubt be raised if more fragile cases are used. Comb honey is not packed in as heavy crates as other goods of light weight and fragile character.

Neither do I think the grading-rules draw the lines too fine or specify too many grades. The rules could be improved; but adopting the "individual" methods would destroy all standards to go by. The development of the modern methods of distribution of fruit and produce has given rise to the grading-rules established by associations of fruit-growers and producers. Take the sections of the country that have distinguished themselves by a certain high quality of product like the Rocky Ford melon or the Hood River apple. These names have been made by the growers combining, and establishing rules and shipping a uniform product.

The apples that are shipped from the West and Northwest have six grades for each variety of fruit—three for size and three for color. That makes more grades than we have in comb honey, and we can not do better than take the hint from the most successful marketers of fruit. There are no pro-

ducing sections of the country in either fruit or honey that have established a name for quality that have not adopted uniform rules for grading and packing, and shipped the goods through producers co-operating to make carloads or organizing an association to do the work.

### COLORADO BEE CONVENTION.

The convention has come and gone, and a good meeting it was too. Often I would hear some one say, "Before another year goes by I am going to observe along that line myself." This is the benefit of a bee convention. By rubbing ideas together we refine our own and get a few additional good ones. Mr. Dyer gave some of his ideas on overstocking bee territory that caused some little discussion. He said he believed that, unless there were bees to gather the nectar as secreted by the bloom, the nectar would dry up and form a hard scale that would stop the secretion entirely. His idea was that the bloom yields nectar for quite a few days, and that the bees get a large amount, comparatively, from each corolla if it is kept empty by the visiting bees. Prof. Gillette said it was the rule for nectar to cease as soon as the flower became fertilized. This, in a large measure, would discount the possibilities that Mr. Dyer spoke of, though he has six hundred colonies in one location at the present time. We shall hope to know more of the outcome later on when he has given the theory a thorough test. The supply of pollen is a more serious matter here in the spring than the lack of nectar in the summer, though we have experienced the lack of both lately often than is desired.

If flowers can be bred up so that the nectar will flow before and after fertilization we shall be well out on the road to more profit from the bee. The cow gives milk out of season (according to the requirements of nature), and we hope the flowers will overstep nature a little for us.

Wilbur F. Cannon, Pure-food Commissioner, gave a talk on the pure-food law and its relation to honey. He expressed his desire to have the bee-keepers co-operate with him in stamping out any adulteration or misbranding of honey.

The most interesting feature of the convention was the lecture by Prof. Gillette on the anatomy of the honey-bee, illustrated with stereopticon slides. The honey-bee is the highest in the scale of all the members of the insect kingdom as man is in the animal. The reason for the classification of the bee at the top of the scale is because she possesses the greatest number of special organs. It is interesting to know that man and the bee have been so closely connected since the dawn of history. Alike in their tastes, social organization, and desires, wherever man has planted trees, flowers, and gardens, there you find the bee. The charm of Prof. Gillette's lecture was the genial personality of the man shining through it all.

\* Mr. Trickey referred to carriers or crates, and not single or double tier shipping-cases.—ED.]

## CONVERSATIONS WITH DOOLITTLE

AT BORODINO, NEW YORK.

### THE VARIATION IN THE BLOSSOMING OF THE BASSWOODS.

It was with more than usual interest that I read what Messrs. W. J. Green and A. I. Root had to say about the basswoods on page 442 of the July 15th number of GLEANINGS, as I have been brought up with the basswoods during the whole of the 63 years of my life. Among the first recollections of the old childhood home is one of my father showing mother a bunch of basswood blossoms and describing their beauty and sweetness to her, while the next spring a tree of this variety was set out near the corner of the house in which I was born. This tree is now some forty feet tall, and nearly or quite three feet in diameter. Later on, father built for himself another home, and in the spring of 1869 set out two basswood-trees about twenty feet from the house, while in the spring of 1874 another tree was set about 100 feet away, at the roadside, as an ornament and for shade to "any weary traveler" who might pass along the public highway, as my father always considered the basswood as the prettiest and nicest of all trees for shade. The two trees nearest the house are now nearly six feet in circumference; but the one by the roadside has not attained so large a growth, being only about 4½ feet around the trunk. I have thus described these trees so that the reader can the better understand what I am about to say further.

The tree first planted at my childhood home is a mid-season bloomer, and so gives me a certain understanding that the season for basswood nectar is half gone; and during all of my bee-keeping life of forty years it has guided me in not expanding my operations for section honey, but, after this bloom, to begin to contract the surplus apartment to the hives so that the season would not close by having a whole lot of unfinished sections on my hands with only a few salable ones.

One of the peculiar things about the two trees planted in 1869 is that one of them never blossoms at all while the other blossoms every year, and generally in the greatest profusion, with bees at work on it at all times when it is in bloom, while many times the tree at the old homestead will not have a bee on it, and that with the old homestead not 400 feet away. But the part which will interest Messrs. Green and Root is this: That profuse-blooming and always nectar-secreting tree is the earliest bloomer of all the basswoods about here, so all I have to do is to step out 20 feet from the door of the house to know when the earliest nectar from basswood can come in the hive. I notice that Mr. Green says that the European linden was in full bloom at Wooster, Ohio, on July 5, while Mr. Root says that the common basswood was in bloom at Medina, Ohio, on July 6. Well, this very earliest-blooming tree

opened its very first buds on July 12, and was not in full bloom until July 16, 17.

By looking at my atlas I find that Wooster, Ohio, is about 15 miles south of latitude 41, and that Medina is about 10 miles north of the same parallel, while I am about 10 miles south of parallel 43; hence Mr. Green is about 125 miles further south than Borodino, and Mr. Root only about 100 miles. It would hardly seem that a distance no greater than that would allow of so great a variation in the time of basswood bloom, and especially as Mr. Green says that the European variety is ten days later than our American.

I wish to tell the reader of something a little strange: That tree set by the highway in 1874 proved to be the *latest* bloomer of any of the basswoods hereabout; and now this day as I write, July 24, it is bursting its first buds just twelve days later than the very earliest, so that I have right under my observation not only the *first* bloom but the *last*, and thus during the most of my bee-keeping life I could tell at a glance about the probable flow of nectar from the basswood, and govern all operations with the bees in accord therewith. Here I have a difference of 12 days in the time of the blooming of our basswoods, all, so far as I know, of the same variety, while Mr. Green gives only ten days as the difference between the American and European; and this difference is not on account of the later-blooming tree growing "in dense shaded pieces of woodland," as Mr. Root suggests, for all of the four trees spoken of grow right out in "the open," separated from all other trees of any kind or nature. I have just come from the north side of a 12-acre woodlot in which some 300 basswoods grow, where I went before writing this, to see if I could find any thing later there; but there I found only two trees as late as the one by the roadside; and as the earliest bloom is gone and the latest just opening, with the others varying all the way between, basswood can be said to be "in full bloom" at Borodino, N. Y., on this the 24th day of July, while the ten day later European variety was in full bloom at Wooster, Ohio, on July 5. Surely this is a great and varied country, and I realize more and more, as the time passes, that locality does play a very important part with those whose occupation consists mainly of apiculture.

### ANIMATED EGGS, ETC.

In adding a little further to the animated-egg question, let me state that I have for years tested my eggs in warm water, as H. F. Hart mentions on page 417, July 1. All eggs that sink after a fortnight's incubation are of no value; but those which float and are individually seen to wobble (not with any movement of the water) are, of course, alive. A minute or two should be ample time for the chicks to wake up, but they generally begin to bob almost directly, and I have thought the wetting good for them, so long as they were not chilled. But by your instructions I have made a "Root egg-tester," with which I have watched a batch of eggs daily, right through the hatch, and it is simply splendid, so I'll have no further use for warm water in that direction. Thanks for that good article, which is but one among many equally valuable.

Auckland, N. Z., Aug. 16.

## EUROPEAN OR BLACK BROOD.

### Some More Evidence Tending to Show that Requeening after the Alexander Plan will Effect a Cure.

BY DR. C. C. MILLER.

I have an interesting letter from John T. Greene, Interlaken, N. Y., who has been doing some things hardly according to orthodox teaching in his dealings with black brood. He says:

I had six yards the past season in which nearly every colony had the disease. We started in to shake every diseased colony; but when one man, with only his wife to help, undertakes to shake about 300 colonies and care for a yard 50 miles away at the same time, he has got to go some.

We had to shake at "any old time" while daylight lasted, and then found we couldn't quite catch up. At the beginning we disinfected our hives, burning them out with a painter's torch. We also had lots of other work to do while caring for the bees.

Well, to make a long story short we began to requeen with young Italian queens (most of my bees were blacks or hybrids). We then began to wonder if the young queens would not do the business and save us a lot of work. You see we were getting tired, and wanted help. So we began to requeen *and leave all the old combs in the hive*, and were greatly pleased to find about 95 per cent of the colonies thus left without a trace of the disease at the close of a very light buck-wheat flow.

He explains that one thing that led to a trial of this sort of treatment was the fact that the previous year a colony in very bad condition had had a young queen given to it, and some time later he was surprised to find that not a diseased cell was to be found in the hive. He also says that where a colony was weak, or did not clean up, two were united, the stronger being placed on the weaker.

Of course, as he says, it is too soon to say that there may be no return of the disease; but the plain facts that he gives are none the less valuable.

After knowing what a scourge black (European) foul brood had been in the State of New York, I had had some question whether it were not in a milder form in Illinois. According to Mr. Greene's letter there is probably no difference.

According to the teachings of Mr. Alexander, the two essential things in the treatment are, first, strength of colony; and, second, a term of queenlessness. Perhaps he would stipulate a third, the giving of a young Italian queen. My own experience confirmed and emphasized the importance of having colonies strong. But instead of having a colony entirely without a queen for three weeks I would give it a virgin at the end of ten days. Now comes Mr. Greene, who believes in strong colonies, but who makes no mention of any time of queenlessness—merely requeens. At any rate, when a strong colony was requeened a cure followed in 95 per cent of the cases.

The question arises, is the queen diseased or at fault in any way? and is the mere change of queen all that is necessary? It looks just a little that way. A number of times my assistant, upon looking at the queen of a bad colony, said, "How logy that queen appears!" And one out of five of the queens disappeared not many days after being thrown on foundation. It was not superseding; generally no queen-cells were started until after the disappearance of the queen. Were the foul brood bacilli in the body of the queen? If so, they were not in the eggs, for the brood from these eggs was in all cases healthy. Yet it seemed that in some way the queens were weak, and perhaps their worker progeny were correspondingly weak, making a change of queens favorable to recovery.

Yet it is possible that it was not a mere change of queens in the case of Mr. Greene's treatment. It must be remembered that generally, when a queen is introduced, there is a break in laying—practical queenlessness—for a day or more, and perhaps for several days. Even when the new queen begins laying, she is not up to her full count for some time, and a diminution in the amount of brood ought to give the bees a better chance to clean up.

This much seems clearly established: That bees are able to clean out a certain number of cells in European (not American) foul brood. It also seems nearly proven that bees in good heart will clean out all, if there is not too much for them to do, and that a stoppage or diminution in egg-laying diminishes the number of foul cells to be cleaned up, and increases the chances for cure. A practical question is: "How long should a colony be queenless to give it a fair chance to clean up?"

Mr. Alexander's rule was to leave the colony queenless for three weeks. But if I understand the matter correctly, Mr. Alexander had hardly gone beyond the experimental stage, and it is possible that he never tried any shorter time than three weeks. Perhaps he reasoned in this way: "It takes three weeks for all brood to hatch out, so that's the time for the colony to be queenless." But it is just possible that there is little or no chance for conveying the disease from a cell that is sealed, and that eight or ten days' queenlessness will serve the purpose just as well as three weeks. And if there be not too much cleaning up to do, it seems reasonable to believe that even less than eight or ten days may answer, when we take into account Mr. Greene's experience, and also the fact that a number of my colonies that were mildly affected cured themselves without any interference on my part.

Let me give one example of self-cure. No. 100 was foul-broody, but not very bad. July 16 I put an excluder on the hive, and then piled on it four or five (I think five) stories of foul-broody combs. Aug. 13 I took away the upper stories, out of which, of course, all brood had emerged, and then opened the lower story in order to treat it.

To my great surprise, not a single diseased cell could be found in the hive!

Marengo, Ill.

[This is all very interesting. We should be glad to get reports from one or more of the York State inspectors who have had a large experience with this disease.—ED.]

### EUROPEAN FOUL BROOD.

Will the Disease Reappear Among Dr. Miller's Bees?

BY F. H. HARVEY.

I have just been reading Dr. Miller's article in the Dec. 1st issue on his experience with black or European foul brood. I note what he says about shaking the bees directly on full sheets of foundation without putting them on starters first. I have tried it, and have had the black brood reappear in a good many cases. I have also had it reappear when swarms from diseased colonies were hived on starters, both when given the partly filled section-super and when given an entirely new one. This is most apt to occur when the bees are dark or have a queen that is not first class.

If Dr. Miller's experience is like mine he will find more or less of his treated colonies showing diseased larvæ early next spring. If the colonies are reasonably strong, and the queens good young Italians, the disease will disappear from most of the colonies for the rest of the season as soon as honey comes in freely.

Regarding the time of day for treating diseased bees, I have found early morning, as soon as it is light, the best. The bees are easily handled, and do not crawl into one's clothing as they do in the evening.

Battle Creek, Mich., Dec. 6.

[This seems to carry out Dr. Miller's (or, rather, Alexander's) theory that the source of the trouble may reside in a poor queen.—ED.]

### THE DEVELOPMENT OF POLLEN.

Insects Can Not Stimulate Flowers to Develop More Pollen.

BY JOHN H. LOVELL.

On p. 677, Nov. 1, a correspondent raises the following query:

Now, there is one point in connection with the pollenizing of flowers that I have never seen mentioned. The greenhouse men used to scatter the pollen by hand, and get some fruit; but now they generally keep bees, and get much better results than by hand work. Now, is not this the result of the bee working, or exercising the glands of the flower in some way? . . . Who knows but that this moving or exercising of the stamens and pistils causes the pollen ducts to put forth extra efforts? . . . I should like the opinion of some scientific bee-keeper on this subject, as I think it a profitable one for discussion.

A brief outline of the development of the grains of pollen will show that this is impos-

sible. The pollen is not secreted by ducts, and the number of grains in each anther is determined long before it is visited by insects. The manner in which they are formed is as follows:

At first the anther is a mass of small homogeneous cells, alike in size and kind, covered by an epidermis. Soon it becomes faintly four-lobed in cross-section, and a central strand of tissue is differentiated to form the connective or common base. In the mature anther these four lobes become reduced to two, each containing two cavities partially or wholly united. Each of the four lobes of the nascent anther is a center for the production of pollen. The layer of cells directly under the epidermis (the hypodermal layer) produces the pollen grains. The number of these cells varies greatly in different species of plants, from 1, 2, or 3, to many. This plate of cells, of which there is one to each of the four lobes, is called the archesporium. By a series of divisions these cells rapidly increase in number; and the outer and inner layers are differentiated into walls for the protection and nourishment of the primary central layer, which either directly, or usually by three or four divisions, gives rise to the pollen mother-cells.

The mother-cells increase greatly in size, and stain differently from the tissue by which they are surrounded. Their walls thicken, become rounded, and tend to separate from each other. The time required for the development of the pollen mother-cells is from one to two weeks.

Each mother-cell divides into four cells or grains of pollen. In the monocotyledons (grasses, scirpoid plants, and orchids) the mother-cell divides first into two cells, and then each of these hemispheres divides again to form the tetrad of pollen grains. In the dicotyledons (buttercups, roses, clovers, daisies, and deciduous trees) the nucleus of the mother-cell divides at once into four nuclei, and the cell-walls are formed later. Deviations from the number four occasionally occur, and instances are known of 2, 3, 5, 6, 7, and 8 pollen grains arising from a single mother-cell.

The wall of the pollen grain is a delicate structure which soon becomes differentiated into two layers. The outer layer is often beautifully marked in various patterns, and beset with spines and warts. At maturity the pollen-grains become a powdery mass, and the four cavities are reduced to two by the breaking-down of the partition wall in each anther lobe. In rhododendron and some other genera the four grains of the tetrad remain adherent, while in the orchids all of the grains are bound together in packets called pollinia.

The anthers open, or dehisce, in various ways, and the pollen either falls out or is forcibly expelled, or adheres to insects, birds, or other visitors to the flowers.

While only a very brief outline has been given of the development of the pollen grains, it is evident that movements of the stamens and pistils by bees can not increase

the number of grains, since the beginning of each grain of pollen long antedates the first visit of insects to the flower. But while insects can not stimulate flowers to produce more pollen, it may well be inquired whether they can not by selection produce races or species of plants which will yield more pollen than their ancestors. The number of grains of pollen in different flowers varies just as does the number of seeds. By selecting flowers with the largest number of seeds for successive generations the product may be greatly increased. May not the same be done in the case of pollen? Bees, indeed, appear to have done this; for there is a class of flowers called "pollen flowers" which contain no nectar, and which insects, chiefly bees, visit for their pollen alone. Such flowers are the anemone, poppy, St. Johnsworts, roses, mullein, and elder.

In the wild rose there is a ring of many stamens which yield a great abundance of pollen and which bees, especially the less specialized wild ones, visit in great numbers. The rose has proven a veritable thorn in the flesh to both artists and poets. Not long ago the *Youth's Companion*, on its children's page, published a large picture of a rose-bush from which bees were represented as gathering honey. Beneath the bush was a still house from which tubes ran to each flower. After passing through a refining apparatus they were depicted as bottling and carting the honey away. Alas! there is no such thing as rose honey; and, alas for such teaching of natural history!

Again, Bliss Carmen sings of "The Swarthy Bee."

He harries the ports of the hollyhocks,  
And levies on poor sweetbrier;  
He drinks the whitest wine of phlox,  
And the rose is his desire.

Not at all. "He" does nothing of the kind, for the rose is nectarless and the phlox is a butterfly flower. Even art in these days can not dispense with science.

Bees of all kinds (and there are probably at least 3000 species in North America) are dependent upon pollen for brood-rearing. Deprived of pollen this entire group of insects would doubtless disappear. The females, therefore, for a part of the time are compelled to collect pollen diligently, and the pollen flowers seem to have been developed to meet this demand. In the tick-trefoil (*Desmodium* or *Melbomia*) when legitimate visitors alight upon the flowers, which are nectarless, the pollen is forcibly discharged by an elastic mechanism. There are many other pollen flowers, some of which have a part of the anthers more brightly colored than the others, to attract the attention of insects.

In conclusion, then, while insects can not, by irritating the anthers stimulate an individual flower to the production of a greater quantity of pollen, yet there seems to have arisen, in response to their demand for pollen, a class of flowers producing this food substance only.

Waldoboro, Maine.

## ROBBING CURED.

### A Change in the Position of Colonies that Resulted in the Complete Mystification of the Robbers.

BY G. A. HUMPERT.

Failures often teach better lessons than partial successes. It was owing to my inability to stop robbing this year that I finally learned something. Doubtless owing to the absolute honey dearth in my locality, and the half-starved condition of many of my colonies right at the time when white clover should be yielding, that robbing became a common event this past year. I vainly tried every means that I had read of except to imprison the robbed colony in the cellar for several days. I didn't try this, for the simple reason that I considered failure almost better than to send my bees to jail when the next few days might bring the expected honey-flow. So I usually had to break up the robbed colony in the end.

But one Sunday morning, when I found that No. 39 was being held up by an overwhelming force, I began to experiment. Reasoning that if exchanging a weak stand with a strong one was a good method of strengthening the weak one, then why not resort to this to stop robbing? No. 38 happened to be a very strong colony, so I promptly exchanged them; then I sat down on No. 38 and watched proceedings, and for five minutes I enjoyed myself hugely. The inhabitants of No. 38, after moving, poured out upon the platform by the thousands, doubtless wondering whether Mr. Williams was there to shake them or what. The robbers filled the air, they came from all directions, doubtless returning for more booty after carrying loads of it home, and, of course, they now all went for No. 38—the colony they supposed had been conquered; but, ah me! their reception was more than warm—it was blazing hot. It did me good to see them yanked about by their antennæ, legs, and wings, and to be forced to give up any little lunch they might be carrying with them.

The lambasting those robbers got was a sight worth seeing. No. 38 poured out more defenders, and the robbers began to entertain doubts of their welcome or the justice of their cause. They no longer dared to alight on the crowded platform, but zig-zagged back and forth with that slow approach and quick retreat so characteristic of the experienced robber. Finally, noting that No. 38 was fully able to care for itself I glanced at 39, and saw that every thing was quiet.

I patted myself on the back, returned to the house, and told Mrs. H. about the great trick I had played upon the robbers; then I went to church (for I hold that a bee-keeper needs all the religion he can get when his subjects take to robbing). However, when I returned I had reason to be thankful that I had had my laugh first, or I should have missed it; for there was poor 39 again being overwhelmed. I became desperate—snatched a screen the size of a lid, raised the hive from the

bottom-board, and slipped the screen between them while the outside robbers were vainly trying to get in, and the robbers inside as vainly trying to get out. I sat down and studied the matter over. Of course, it was plain enough that, when I moved 39, I had moved the robbers along that were then in the hive. They hadn't had time to tell their kith and kin of the new location of booty before I left, hence the seeming quiet at that time.

I looked at 38, all serene; and if a stray robber came within hailing distance of its strong guard he apologized immediately under pretense of a mistake, and went about his other affairs. The exchange of hives had struck me as very good strategy, and I was loath to acknowledge another defeat; but how to deal with the robbers inside of the hive when moving it—that was the problem. Reasoning that every bee—respectable or not—certainly wants to go home at night, I had previously tried moving robbed colonies before after dark, and failed to stop the robbing. Why? Did the robbers simply find the weak and demoralized colony again on the following day? or did some robbers lodge there over night? If the former, then a simple exchange with a strong colony after dark would do the trick if the latter—aha! I had an idea. I waited until dusk, when the bees stopped flying, but before it was too dark for them to find home. Then I went to 39, now quiet save the complaining murmur of imprisoned robbers and the disconsolate roving of a cluster between the screen and bottom-board—some, doubtless, from 39 that had been locked out, but the majority were field-bees from 38, the latter being pure Italians and the former blacks. I took the lid off, and a swarm of robbers instantly took wing. To make sure that all should have a chance to go I got an empty hive-body, stood it in place of 39, shook each comb in front of it, and put it in the new body, closed up, and left them for an hour to quiet down; then I exchanged 39 with 52—another strong colony—and contracted 39's entrance.

The following day I watched with interest, and, behold! it was a complete success. Since then I have employed this method a number of times without a single failure; in fact, I now consider the robbers as my allies. They promptly point out any weak colonies that need strengthening; but now, instead of shaking the combs, I simply take the lid off at dusk, give the hive a jolting, and make the exchange at once. To facilitate matters I have on hand a few wire screens nailed to frames, lid size, which I can easily slip under the hive. These are employed if the robbing is started early in the day; but if in the evening I simply contract the entrance and make the exchange at dusk.

Pittsfield, Ill.

[Your scheme of curing robbing is something similar to one described by A. I. Root in the original edition of the A B C of Bee Culture, with this difference, that he put the robbed colony in the place of the one that was *doing* the robbing. As we understand

your plan you simply put a strong colony, no matter where it is, whether engaged in the robbing or not, in the place of the one that is being robbed because it is weak and unable to put up a stiff defense. We are not sure that we have seen this before described in print, although we would be of the opinion that others had probably tried it. In a general way we think that the plan is good.—ED.]

### "WEEPING" HONEY NOT NEW.

BY J. D. FOOSHE.

I note in GLEANINGS an experience by H. F. Hart with what he calls weeping honey. I have had just such an experience with this kind of honey only once in my long time of bee-keeping. About 18 or 20 years ago all the honey in my apiary, both sections and brood-combs and extracting-combs, were filled with it. I tried every way I knew to extract it, and finally gave it up and let it go back on the hives for the bees to use up during a dearth afterward. I wrote to GLEANINGS about it, and I think there were several others who had had the same experience. I do not remember now what suggestion was made by A. I. Root; but you will find somewhere on file my enquiry and his answer. I think that the article is entitled "Honey from Persimmon going to Sugar."

I was satisfied at the time that the honey was from the persimmon. We had a peculiar condition of the atmosphere that caused it, just as it happens that some years we have honey-dew, and perhaps for several we may not see a trace of it again. This year we have had more than for several years; in fact, I have been troubled with honey-dew but once or twice in all my bee-keeping experience, and only once with honey that acted as Mr. Hart reports. I think the whole trouble comes from atmospheric conditions.

I also think the so-called bee paralysis is caused by atmospheric conditions. Several years ago this disease was raging south as well as north; and I saw it about in neighborhoods, and one or two years I saw two or three colonies in my own apiary during the fall; but for years I have seen no trace of it, either in my own or neighboring apiary.

### THE SEVEN-TOP TURNIP AS A HONEY-PLANT.

My good friend A. I. R. has requested me, page 484, Aug. 1, to give my experience and observation with seven-top turnip as a honey plant. The interview published in the State last spring has called forth replies, so I will, in response to friend Root, tell what I know in regard to this plant. I have for years, perhaps ever since I have been handling bees, at least 30 years or more, planted seven-top turnip for the seed alone which I sell to seedsmen, and find for this purpose it has been a very remunerative crop; but a few exceptions to this rule.

It is the earliest plant we have to bloom, beginning about the middle of March and lasting until the middle of April; and it

blooms more profusely during that time than any thing I know of, and bees have a good time gathering pollen and some honey from it. Honey enough to encourage brood-rearing, bees soon build up on it to the swarming state. I find that our late cold springs in the past few years, with heavy frost about the time turnip and fruit bloom are done, often kill all remaining flowers which bees are dependent on, and they are left in a worse state than had they not been stimulated so early. I find, also, that, while turnip is not a legume, yet it is a fine crop for a cover crop; and corn or cotton grow luxuriantly after it. I harvest my turnip seed about the first week in May, and land is then available for other crops. I have made all the way from 100 lbs. per acre to 400 lbs. I usually sow 15 to 25 acres without fertilizer; but if well fertilized and cultivated I don't know the possibilities of yield. I usually prepare after stubble. I mailed my son some seed last year in St. Paul, Minn., and he planted them in the spring, and reported they made fine seed. I usually sow here from the middle of August to the middle of October.

Coronaca, S. C., Nov. 7.

## BULK COMB HONEY VERSUS SECTION HONEY.

A Locality where there are Several Short Flows is best Suited to the Production of Bulk Honey.

BY J. J. WILDER.

There are many locations where the production of comb honey in sections is very unsatisfactory, either on a small or large scale. Also the production of extracted would be equally unsatisfactory on account of the condition of the market, etc.

The production of section honey is not suitable for the farmer bee-keeper, busy man, or those engaged in bee-keeping in a slipshod way as a rule; and in the majority of cases the production of extracted honey would not suit.

There can be no doubt that there is a lot of dissatisfaction among the smaller bee-keepers over the modern hives they are using. The hives such bee-keepers generally select are those the supers of which are for section honey in some of the many styles.

It would be far more satisfactory for this class of bee-keepers to produce chunk or bulk comb honey in modern hives. It would be more economical, simple, and would give greater returns; and it is hoped that the bee-supply manufacturer will list a bulk-comb-honey super, and advocate it.

In localities where there are from two to eight light and short honey-flows at intervals during the entire season (the writer lives in one of these locations), the production of section honey can never be satisfactory; for as soon as the bees get to storing in the supers the flow is on the decline or off; and

perhaps in two or three weeks there is another such flow, with possibly a "flow" of propolis between each one. At the end of the season there are more partly filled sections than full ones, and may be those that are filled have several different kinds of honey in them, and they will not bring a fancy price.

In the production of bulk comb honey all the surplus honey can be removed at the end of each flow, whether the frames are full or not, and the honey is as nice, for it can be saved and will bring its full market value.

There are many bee-keepers in locations where the most of the honey is dark. If they would produce bulk comb honey, and can it, it would bring more on the market, and be a much better article.

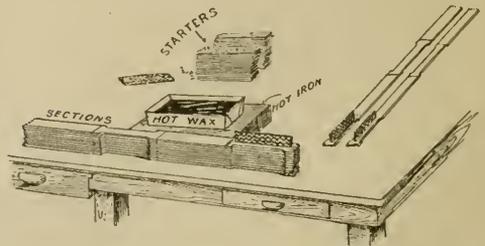

Dealers are "kicking" against shipments of dark honey in sections at any price, and soon the bee-keepers will be compelled to put it on the market in different shape.

It has been our experience that comb honey in bulk will sell wherever section honey will, and there is no reason why it should not. It is more wholesome, can be better exhibited, and it will keep longer. It is not a question whether we shall produce more extracted honey and quit comb honey in these sections less favorable for its production. We should produce more comb honey, for we would soon glut the market for this grade of extracted honey. But how can we best supply the demand for comb honey? I would suggest the old-fashioned chunk honey, which I believe will win out in the long run.

Cordele, Ga.

## PUTTING IN STARTERS BEFORE THE SECTIONS ARE FOLDED.

In placing sections in a super, p. 263, May 1, I believe the joints should be placed down. This prevents the bees from daubing them over with glue. They never seem to know when they have enough on; and if the sections were very dry, as I have sometimes seen them, the joints would be so loose they would spring apart before the bees would get around to glue them. The result then is, that the top of the section will be fastened to the super above it.

When placing only one starter in a section after being folded (page 263), did any one ever try putting in starters before folding sections? I can put in starters faster than two men can fold them. This is the way I do it: Pile up the sections evenly in stacks of about ten. Have a dish of melted wax on a hot iron to keep it liquid. Piles of starters should be in easy reach. Take a stack of ten sections. Place them on a table close to the edge of the dish of wax, and pick up a piece of foundation. Dip the edge in the wax and then stick it on the section quickly.

WAHL'S HONEY AND BEE DEMONSTRATION EXHIBIT IN THE ROCHESTER INDUSTRIAL PARADE.

### HANDLING BEES ON A FLOAT IN A COMMERCIAL PARADE.

#### A Form of Advertising that Pays Well.

BY LOUIS F. WAHL.

So much has been said through the bee journals about advertising honey that I have decided to add a word to the discussion. In Rochester, N. Y., there was a parade, October 19, of historical and industrial floats, which in every way was a triumph of art. There were 122 floats, each one representing some phase of Rochester industry. As much as seven hundred dollars was paid by some of the department stores in the decorations of their floats, the main object being to advertise. It was estimated that 100,000 people gathered to view the procession as it went by. I will describe my honey-float, as shown in the engraving, and tell something of its cost.

In the first place I paid \$1.50 for second-hand lumber. The painting of the signs cost \$3.78; the oilcloth, \$3.24; the carpet, \$1.50; cheese-cloth, \$2.25, making the total cost of material \$12.27. The best part of it is that all this material can be used again for other purposes. It took my brother three days to do the carpenter work, and Mrs. Wahl did the trimming.

The rack or floor of the float was 12 feet long, 7 feet wide, and just cleared the wheels. At each corner a 2x3-inch post, 9½ feet long, was placed, the lower end extending 2½ feet below the floor. To the bottoms of these posts a strip was bolted, on which

to tack the oilcloth so the wind could not blow it against the wheels. Also on the tops some strips were fastened for holding the signs. The color of the trimmings was that used throughout the whole parade—lavender and white.

During the parade, two boys in front, each sitting on a bee-hive, were eating comb honey, illustrating the fact that "the proof of the pudding is in the eating." My niece, who stands at my left in the illustration, did the uncapping; the young woman in the center changed the combs, while Mrs. Wahl did the extracting.

To hold the attention of the crowd we had a wire-cloth cage (the one which I used a few years ago for demonstrating in a department store). Inside this was a colony of bees, and during the parade I took out the combs, bees and all, held them up so that all could see, and also scooped up the bees with my bare hands. I doubt if half of the crowd noticed the float which followed ours. I could see people looking and poking one another, and exclaiming about the bees. One policeman stepped up close to the cage, then rushed back, brushing himself as though twenty stings had reached him at once. When we reached the courthouse, where the mayor and the officials of the Chamber of Commerce were sitting, reviewing the parade, they all took off their hats and cheered us. Although it was so cold, cloudy, and windy (about 40 degrees Fahr.), that we had to be bundled up to keep warm, the bees did their part well. If sills rest directly on the ground, but the plat-

LEWIS P. TANTON'S APIARY IN PRINCE EDWARD'S ISLAND.

any of them took flight in the cage they struck the screen and fell to the bottom where they clustered together to keep warm.

This method of advertising is just the kind that pays, and, in my opinion, it is worth ten times the cost of any other kind. After a sensation is created, no one talks about the purity of the honey or questions the price. If people like honey at all, it is necessary only to show that you are the "honey-man," and prove it by exhibiting the picture of the float.

I have never yet been afraid to tell others about bees for fear they would go into the business for themselves. The fact is, most people are afraid of the stings; and unless they are so interested that they stay up nights to read and study, they make a failure in the beginning, and quit. Then if, by chance, one happens to master the situation, he will soon find out that overstocking is a bad thing, and he will buy out some beekeeper or seek an unoccupied territory.

Chili, N. Y.

#### THE EFFECT OF COLOR ON BEES.

#### The Strongest Colonies Found in Blue Hives.

BY LEWIS P. TANTON.

I was interested in the article on page 543, Sept. 1, covering experiments as to the preference of bees for particular colors. Whether or not they have any particular tastes along this line I will not undertake to determine. That blue hives, under certain conditions, are more profitable than white, I must admit that I entertain very strong and perhaps well-grounded suspicions. Being rather

cramped for room I have had to keep my hives very close to each other. In order to prevent confusion of the bees in recognizing their homes I have all my hives painted alternately white and blue. I find a tendency to be that they work stronger, both in bees and honey, in the blue hives.

In 1908 I chanced upon a fairly good evidence in this direction. June 13th I placed a three-frame nucleus in a white hive, and on the same day a two-frame nucleus in a blue hive, both upon the same stand, not two feet from each other. The white hive gave me about 80 lbs. of surplus honey and one natural swarm, on Aug. 16. My two-frame blue hive produced over 100 lbs. of surplus honey, also one colony, by division July 28, and a natural swarm Aug. 15. But some one will answer, "One of your queens was superior to the other." This is also true; but the poorest queen, as shown by after-performance, was in the blue hive. This year I have had to feed her and all her increase to fit them for their winter rest, with the one exception of the daughter remaining in the old blue parent hive, which is full of her own honey and bees, and in good wintering condition. All her other stock are in white hives. On the other hand, the queen in the three frame white hive and all her progeny have turned out to be prolific layers and princely workers—the best in my garden. From one of her daughters in a blue hive I have this season taken more honey and more brood than from any other two hives in my apiary combined. This queen I lost by accident early in the season; but every one of her issue has given me a fair surplus of honey and an increase, in spite of a very poor honey season.

My apiary has a sheltered and shaded loca-

tion, and I conclude that dark colors attract the heat, from which this advantage comes, and are best adapted to northern latitudes and cool locations. In a hot sun-visited locality the white hive might be best. I choose the blue because it suited my taste. It seems to please the bees also.

As you probably do not hear very often from this quarter of the globe I am enclosing a snap-shot of my apiary of 22 hives. It is not a very large showing, it is true; yet it is the largest, I believe, in this Gem Island of the northern gulf.

Charlottetown, P. E. I., Oct. 23.

[That darker colors usually absorb more light than lighter ones must be admitted; and yet it is a fact that light blue, yellow, etc., reflect the light and heat almost as much as a pure white. The engraving from the photograph of the apiary illustrates this very nicely, for it would be difficult to pick out the hives painted blue, showing that the blue color reflects practically as much light as the white.

Mr. Lovell, in his experiments described in the Sept. 1st issue, as above mentioned, demonstrated that his bees preferred the blue paper. Is it not possible, then, that the bees in this case, preferring the blue color, naturally "drifted" into these hives? If all

the hives were painted blue it is doubtful whether there would be any advantage.—ED.]

### HOUSE-APIARIES.

#### Something More Concerning their Advantages and Disadvantages.

BY B. M. CARAWAY.

I have had just four years' experience with a house-apiary, and, taking every thing into consideration, I think that the disadvantages more than offset the advantages. My building stands north and south, with the hives facing the east and west, the alley between running through the center. On each side there is room for ten hives.

When I built this shed I thought it would be a good plan to have doors that could be let down during the winter; but I have found that, in this southern climate, this is not a good plan. The temperature may be down to the freezing-point in the morning, and at noon it will be so warm that the bees will be trying to get out. For this reason I keep the doors propped up all the time.

The building proper is 32 feet long, 6 feet wide, and the side walls are 6 feet high. The

MR. B. M. CARAWAY'S HOUSE-APIARY IN TEXAS.

Mr. Caraway believes that, if he were starting anew, he would put his money into better bees and fixtures rather than into a house-apiary.

forms on either side, on which the hives rest, are swung from the joists overhead by means of  $\frac{3}{8}$ -inch iron rods 42 inches long. My idea in constructing the hive-shelves in this way was to keep the ants out of the hives. I have found that it would have been better if I had had a circular piece of tin soldered around each rod near the top so as to make a sort of

cup that would hold some material which would prevent the ants from getting down. The bottoms of the hives are just 22 inches above the ground, but five or six inches would have been sufficient.

In mentioning the advantages of such a building I may say, first, that the most vicious bees are much gentler when handled

FIG. 1.—POUDER'S HOT-AIR OVEN FOR LIQUEFYING HONEY IN SIXTY-POUND CANS.

The cans are held upside down, as shown in Fig. 2; and the honey, as fast as it becomes liquid, runs down to the bottom of the oven and from thence out the gate, away from the heat.

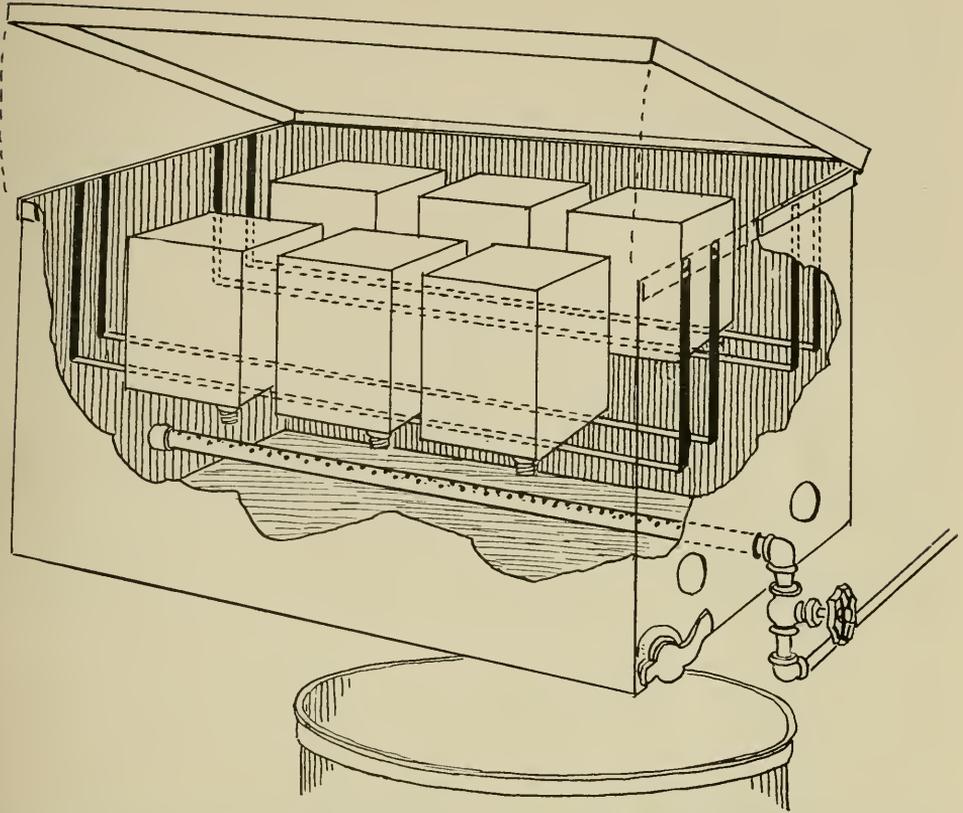

FIG. 2.—POUDER METHOD OF LIQUEFYING GRANULATED HONEY, SHOWING THE POSITION OF CANS AND GAS-BURNER IN THE OVEN.

in a house-apiary. Second, work can be done in any weather, wet or dry. Third, there is no danger of honey melting down caused by the heat. This is a most decided advantage here in Texas. Fourth, the hives need no painting, and will never rot; they are practically everlasting. Fifth, there is no danger of stock knocking over the hives and being stung to death. Sixth, in case thieves are troublesome it is not difficult to prevent them from getting in. Seventh, the bees do not consume quite as much honey in winter as they do on separate stands out of doors, the reason being, probably, that they are less apt to fly out in cool weather, and are, therefore, quieter.

Now for the disadvantages. First, the shade is too dense in the early morning. The bees in the hives outside are working about an hour before those in the building begin. Mr. Alexander never spoke a truer word than when he said that the early morning shade is detrimental to bees. Second, the bees outside gather the most honey. Third, the hives outside can be manipulated the quickest. Fourth, the expense of a building of this kind is no small item. Fifth, many bees get into the wrong hive, and there is apt to be mixing up, which, if honey is not

coming in, results in fighting. Young virgins, also, may get into the wrong entrances and kill the old queens. I have painted the fronts of the hives different colors, but this does not seem to remedy the trouble. The building is not sheltered from the winds, and sometimes when there is a stiff breeze from the south the bees are blown on toward the north end of the building, and thus get into the wrong hives. I intend to move the apiary to the woods in a more quiet location.

Summing it all up, it is my belief that, if a man has money to build a house-apiary, he had better put it into more hives or better queens or bees, or something else that is needed. I think that the beginner especially can spend his money in better ways than by putting up a building of this kind.

Decatur, Texas.

### LIQUEFYING GRANULATED HONEY.

BY WALTER S. POUDER.

For years I have depended upon the hot-water tank for melting five-gallon cans of granulated honey, but have found many inconveniences connected with the method, and have been obliged to adopt a safer and

FIG. 3.—SAMPLES OF PAPER MILK-BOTTLES SUGGESTED BY WALTER S. POWDER, FOR RETAILING LIQUID HONEY.

The stopper is crowded tightly into the small end with the wooden plunger. When clear in, it is impossible to remove the cap without the use of a knife or screwdriver. The cap is put on the small end to reduce the liability of leakage.

speedier method. To take care of the expansion I have used syphons, coal-oil pumps, funnels soldered to perforated screw caps, and other methods, but have always found a lack of tidiness; and in some instances we have ruined very superior honey by overheating. If we overlooked a nail hole near the bottom of a can we would find a can of sweetened water instead of honey; and in lifting heated cans from the water I have had the handles pull off; and the can, in falling back, would cause the hot water to slop over and scald my toes till I have seriously wished that I did not have to dabble in honey at all.

I have longed for a method in which the liquid honey would flow away from the heat as fast as it became fluid, and at last I have such a device in use, and I believe many readers of GLEANINGS will be interested. It is simply a gas oven, made of heavy galvanized sheet iron, and of a capacity for six cans, three on each side of the gas-burner, cans to be suspended on brackets in an inverted position with caps removed. When in use the honey-gate at the bottom of the oven is left open; and as fast as the honey becomes liquid it flows to the outside tank. Considerable experimenting was required in order to maintain proper temperatures, and we have learned to regulate the temperature by using a thermometer before we place any honey in the oven. Naturally the highest temperature is nearest the top of the oven, and we are able to keep within 180

and 190, and the temperature declines toward the bottom of the oven, hot air being circulated throughout. Some heat is slightly radiated against the lower part of the cans, and I find this in my favor, as it tends to prevent openings of cans being clogged with granulated honey.

The two round openings in the front are for ventilation, and to secure perfect combustion. There is a three-inch space between the burner and the bottom of the oven. Cans are suspended with a thirteen-inch space between the bottoms of the cans and the bottom of the oven, and a two-inch space over the tops of the cans; and there is also a twelve-inch space between the two rows of cans. We also find the device very convenient in melting jars of granulated honey without so much as injuring the label by simply inverting the open jars on a heavy wire screen.

Such an oven could be constructed for any capacity—for two, four, or six cans at one time, and could be used over a gasline-stove where gas is not obtainable. A thermostat could be added, thus making it an automatic arrangement; but in my business I have not found it necessary. The honey, as it flows into the outside tank, is just right to be strained into our bottling-tank, and there is no deterioration, because it could not be overheated.

Visiting bee-keepers pronounce the entire arrangement a model of perfection, and I submit the above description by request.

#### PAPER MILK-BOTTLES FOR EXTRACTED HONEY.

Since Mr. J. E. Crane introduced the paper milk-bottle for extracted honey I have felt much interest in the affair; and a manufacturer of this ware has supplied me with a liberal lot of samples which I have been testing. In my opinion this bottle will fill a long-felt want where honey is offered at retail, and at such places as market-stands, for a great many people would like to take home with them a pound or so of honey if a neat container could be furnished without cost. I have used paper oyster-pails for this same purpose; but removing the honey from an oyster-pail is always untidy at the best, while the waxed bottle is very neat and attractive, and easily drained into a dish.

I believe there are several patterns of these bottles now being offered, of different sizes and shapes. The ones that I have been using have a neat paper stopper, Fig. 3, which could be sealed with hot paraffine if so desired. I also find the package very desirable for granulated honey in a damp climate such as we have here, and jars could be filled while honey is semi-granulated, and then allowed to granulate completely; and in preparing for the table the waxed paper could be easily removed. If made in quantities, suitable reading-matter could be arranged, leaving a blank space in which the producer could stamp his name.

While I have not tested these jars as to shipping qualities, I feel sure, that they would stand all requirements. I will explain that I have none of these jars for sale, but I believe they should be classed along with our honey-packages; and when understood they will be in demand, and they will fill a long-felt want.

Indianapolis, Oct. 14.

#### ARTICULAR RHEUMATISM RELIEVED BY BEE-STINGS.

BY W. A. PRYAL.

To have rheumatism and suffer its slings and pains, or take up a few live honey-bees and banish the tormentor with some well-directed stings, is a question that even the learned men of the medical profession can not agree upon. So when doctors disagree, we are sure to be badly at sea, to put an old saw in a slightly changed form.

The efficacy of bees' stings as a cure for rheumatism is again being discussed in this country and in Europe. In the September number of the *American Bee Journal* Dr. A. F. Bonney gives a lengthy argument on the negative side of the question. Dr. C. C. Miller, the noted apiarist and writer, takes up the same question in the October issue of the magazine named. The latter does not entirely agree with the first writer. He refers to the favorable position of the European medical fraternity in regard to the benefit of bee-stings in the cure of rheumatism; also to the fact that the preponderance of

evidence in this country is on the affirmative side. Thus the doctors stand. Who is to decide?

We of the laity bee-keepers have generally believed that the bee would drive rheumatism from our afflicted bodies; and still some apiarists have been as full of "old rheumatiz" as those who were never pricked by a bee. However, I am able to report the case of one who has shown bravery, inasmuch as the patient suffered the stings of thousands of bees in order to regain her usual health. This case has come under my observation during the past summer.

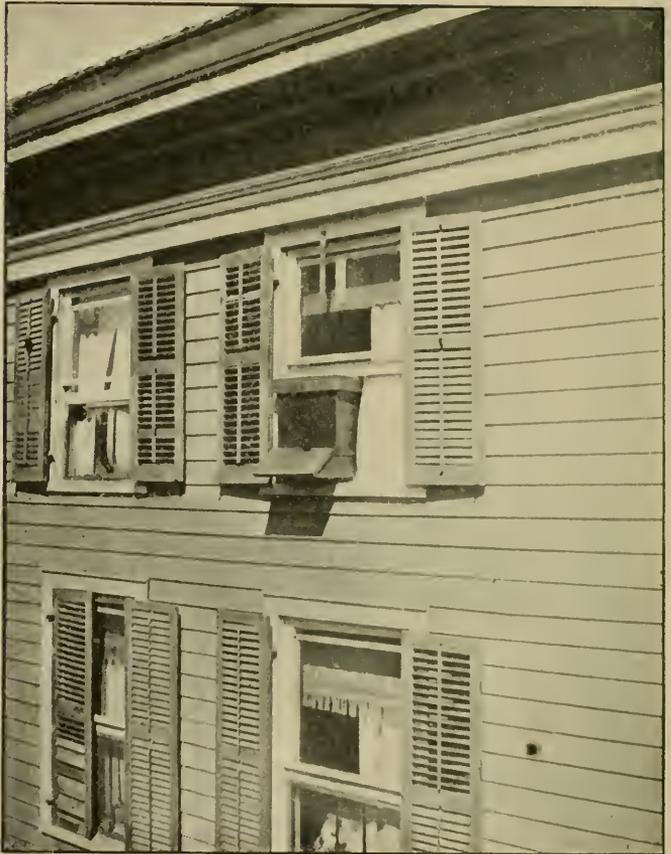

Mrs. Mary Ruttenbeck, something less than a year ago, became a sufferer from a very severe attack of articular rheumatism, the main point of attack being in her knees. The malady became so violent that she was not able to walk. The pain at times was excruciating. Her brother, Mr. Piercey, is employed at the Mare Island Navy Yard, this State, and is an ardent tender of a small apiary which he keeps on the island. Having read that bee-stings are a cure for the disease in question he sent for his sister and had her submit to the "honey-bee-sting" cure. The invalid was tenderly brought out to the apiary one fine spring day and seated in front of a bee-hive. A bee was deftly caught and made to jab its sting into the lady's knee. The insect performed its part of the operation in good style. Mrs. R. protested at being made a target for further stings. She thought the pain from one sting was sufficient for her for a lifetime—that it was enough to drive the disease from her.

MRS. MARY RUTTENBECK,  
who endured the pain of a large number of bee-stings to get relief from articular rheumatism.

But Mr. Piercey thought otherwise. He was not planning to practice homeopathic bee-sting medicine—it was to be allopathic or nothing at all. So the stinging went merrily on, the patient all the while almost fainting with the added pain. Mr. Piercey was fast working his bees to death in this new-fangled occupation he had found for them, for he did not desist until thirty-nine stings were duly planted in his sister's knees. Then she was carried away; but in leaving the apiary a bee of its own free will gave the patient a terrible jab in the neck—perhaps for good luck, or, may be, just to say that Mrs. Ruttenbeck “got it in the neck.” Any way, between getting it in the knee and in the neck she was a very sick woman for a few days. It looked for a time as if the cure were going to be worse than the disease.

The turning-point came; and after a few more applications of a less number of stings she was able to walk. She found that it was not necessary to take drastic doses of thirty-nine stings at a time. In June last she came to Oakland. It was about this time that I became acquainted with her, for a friend of hers came to me to procure good strong healthy bees that could be vouched for to sting good and plentifully when occasion demanded. I found a colony of Spanish-blacks that had a small percentage of Italian blood. I gathered some three dozen of them into a cage and told the gentleman to instruct the patient that the bees should be “well shaken before being taken.” The instructions must have been followed, for in a few weeks the lady was able to walk from the electric-car line to my place, something like a third of a mile distant. Since then she has been here a number of times—sometimes to get bees and other times to purchase fruit, for which our place is somewhat famous. On one of these occasions, about noon, which is not the best time to take outdoor pictures, I had her pose for a photograph that the readers of GLEANINGS might see the picture of a California woman who attributes her almost entire cure from rheumatism to the use of bee-stings. Yes, I wanted the GLEANINGS folks, too, to see a woman who had nerve to face a thousand bee-stings, and prove her faith in

A HIVE KEPT IN A WINDOW OF A HOUSE IN A VILLAGE.  
An alley runs directly beneath this window; and, though horses frequently pass, none are stung.

the cure about which the medical profession are in doubt.

Oakland, Cal.

[An article on this subject was published in Dec. 15th issue, page 784, from Dr. Bonney.—ED.]

#### A COLONY KEPT IN A SECOND-STORY WINDOW IN TOWN.

BY C. H. WATSON.

I am a lover of bees; but, unfortunately, I live in the heart of a village. I am sending herewith a photograph showing my colony of fine Italians which I have in the second-floor window on the south side of my home. These bees have been very law-abiding indeed, not even bothering horses that pass in an alley beneath the window. During the past season this spot has been the very personification of industry. These little friends have visited distant hillsides; and as they have returned laden with sweets of a thou-

sand flowers they have taught me lessons of westness and faithfulness.

Westfield, Pa., Sept. 10.

---

### POISONOUS COMB HONEY.

BY GEO. M. LORD.

*Mr. Root*.—Will you kindly tell me what there can be in honey to make it poisonous? Some days ago I took a swarm of bees from the eaves of a neighbor's house. There was about 75 lbs. of apparently fine white-clover honey, most of it in new comb, which had never been used for brood. All of the honey was stored this year, as the swarm came from my yard in May. At least four times I have attempted to eat some of it; but each time within twenty minutes I have been taken with severe cramps and nausea. Others to whom I have given the honey have experienced a like result.

I find after the honey has been extracted by melting on the stove it loses its poisonous quality. Whether due to the heat used or to the absence of the comb I can not say.

Although the party from whose roof I got the honey sold and gave away about fifty pounds to at least a dozen different people, yet there were only two besides myself who suffered any ill effects.

Wells, Me., Nov. 2.

[We asked our correspondent to send us a sample of this suspicious honey; but after eating quite a little of it we experienced no very bad result with the exception of a slight "gnawing" sensation. Others who tasted the honey could detect nothing wrong. We finally sent the sample to our chemist, W. A. Selser, knowing that he could probably find the trouble, if any. His interesting reply follows.—ED.]

*Mr. Geo. M. Lord*.—I have put the sample through my laboratory, and just completed the analysis. I find this is absolutely pure, and there is absolutely no poison whatever in the liquid honey. There is a good amount of sucrose, but not above the normal quantity allowed. So I should report it a pure sample in every way.

While there was not sufficient wax to give as complete an analysis as I should like, after separating, washing, and cleaning it from the honey and residue I saw what I would call traces of vegetable poisoning, but in very small amounts—not large enough to determine the quantity.

I had a sample which I think was analogous to this about fifteen years ago, and probably a few remarks about it may be helpful to you. A case of violent cramp and poisoning, where several parties were stricken down and kept in bed from one to three days, was reported to me in Trenton, N. J.—said to be the result of eating comb honey. I immediately went to Trenton, and, after following up several clues, found the honey was from near Hammonton, N. J. I also found upon investigation that the trouble

was caused by the wax, not the honey itself. After driving for miles through the country surrounding Hammonton, on inquiring of the different bee-keepers I found this honey had come from one source. It was gathered in the lowlands at a time when the bees were working on a plant somewhat similar to our mountain laurel. Honey gathered from the same location, although possibly not exactly from the same source or under the same conditions, has been sold and consumed since without giving any trouble.

### COTTON AS A HONEY-PLANT.

A Fall Crop Produces More Honey than That Grown at the Regular Time.

BY D. P. HUNT.

Noticing the enquiry of D. D. Stover and your reply thereto, Nov. 1, page 676, I will say that to-day, Nov. 11, the bees are getting honey from cotton as fast as I have ever seen them gather it from any source. It is water-white and of fine flavor. About ten days ago I discovered my bees were busy, and going south from town. On investigating I found they were going to some cotton-fields about 1¼ miles distant, where there had been some pretty good showers during the latter part of August and first of September, sufficient to cause a rank second growth, and it was covered with bloom. I came back and moved one load down there, and set them out right in the field, and will carry another load to-night.

I have kept bees some 20 years; but being a druggist I have had very little time to devote to anything else; but having lost my store by fire last year I purchased some more bees and have become quite a bee crank. Last season, 1908, was the best I have ever seen; this season was the worst. Up to Aug. 20 we had hardly rain sufficient to lay the dust. All crops and even the weeds failed to grow; but cotton will stand until frost; and if it gets rain in the fall it will grow fast. I believe the fall bloom will yield more nectar than it does at its usual blooming time which is from May to July, as the long hot days seem to dry up the secretions, and, as a general thing, there is an abundance of other bloom during those months in this locality, and it would be difficult to say that you had any real cotton honey.

But there is no mistake about it in the fall, for there is absolutely nothing else to work on. I have watched the bees at work on it for hours. During the last few days they do not seem to care much about the inside of the bloom, but prefer the nectar-glands at the base of the corolla, and outside, also, on the buds or "squares."

There has been a great dearth of pollen all the season, and the bees are in great need of it. They are searching far and near for

it; but if they got any from the cotton bloom it has escaped me.

In conclusion I am sure that in any year or any locality where cotton has sufficient moisture to induce vigorous growth its bloom will yield nectar; and in the fall months, with cool nights, it will yield abundantly.

Blum, Tex.

[From various reports that have been sent in we have been led to believe that honey from cotton is of indifferent flavor. We should be glad to get reports from others.—ED.]

## THE BEST PLACE FOR BAIT SECTIONS.

### A Valuable Article.

BY H. E. CROWTHER.

As to the best place in a comb-honey super (corners or center) for bait sections I am inclined, after using them both ways, to do as Mr. Bevins does. He says, "Last year I put the baits in the corners; but the results were not satisfactory. Some were untouched when the rest of the super was finished, and many were left uncapped. Bees naturally begin work in the center of the supers, and that, I believe, is the best place for baits."

I think the object of bait sections is not to get the super filled out at the corners but to get work started in the super, and the *corners* will take care of themselves. Later, if the honey-flow amounts to any thing, and if it is poor, possibly the four-cornered super would be left empty instead of half full like the one with a good start in the center.

### SHORT SPLINTS PREVENT BUCKLING.

I have had no trouble with buckling in using five-inch splints, as has Dr. Miller. I used them on both medium-brood and light-brood foundation. The frames were wired with three horizontal wires, two of which helped support the splints, and were all that are necessary, I think. I intend using, the coming season, two wires and five short splints. Combs nearly always break within two inches of the top-bar, and with four or five splints reaching well below this weak place and supported by the wires very few combs will ever break; and splints of this length are much easier to apply. I have yet to find any poor combs built over this arrangement. Of course, another season may be different; but I will try it anyhow.

Unsplinted combs that break near the top-bar will be quite well fixed up if they can be put in a strong colony upside down for a while and properly spaced; otherwise it is a waste of time to put them back at all.

### EXCLUDERS DO NOT INTERFERE WITH THE STORING OF HONEY.

I would not do without excluders on extracted-honey colonies, and have not found them to be honey-excluders. If a queen goes above (that is, I mean when excluders are not used) she gradually deserts the lower hive; and the addition of another body of

empty combs on top only invites her higher up. When we come to extract, the colony is in any thing but an ideal condition, with brood scattered through the whole hive; and if the extra bodies of combs have been spaced wide they are not in the best shape for a brood-nest, even if brood were wanted here. Many of the extracting-combs we use are not suitable for brood anyhow—mainly because of drone-cells or a great plenty of sagged cells in the upper part (unsplinted combs).

The presence of drone comb in the super is not the whole cause of queens going up, for they work up just the same with all worker comb above.

### DOES THE DISTANCE BEES FLY HAVE A BEARING ON THE AMOUNT OF HONEY GATHERED?

A friend of mine has a homestead three-fourths of a mile above the irrigation canal, and has 150 colonies of bees on his place.

This year his crop was about one-third as good as the average from well-cared-for bees kept below the canal among the alfalfa-fields. Has this short distance made that difference in the crop? There is nothing above the canal for the bees except a few early flowers for breeding up in the spring. His crop the year before was somewhat better. The bees, of course, get less than half a range, but I know of bees located directly on the canal with only half a range that do as well as full-range yards in the same neighborhood. Does the bare half-mile make the difference?

Will three yards of bees produce less honey if located too close together in a straight line than the same bees would if all were in the two end yards, by reason of the bees in the middle yard being handicapped by coming to the dry streak on each side, and not passing over, so losing all benefit of the range further out?

Another neighbor had a queen-mating yard seven miles back in the hills, and he says that even his nuclei carried plenty of alfalfa honey from the valley seven miles away.

Parma, Idaho.

[In answer to your question whether the bare half-mile from the forage would explain why those 150 colonies did not do better, it would seem hardly probable. If there were other yards, the bees of which were located nearer the same range, then it would be easy to see why bees further or half a mile away should not do as well. This is an interesting subject for discussion, and we hope that some of our readers in the alfalfa regions will give us data.

We should also like to get further reports on the question whether queen-excluders are also honey-excluders. The mass of evidence so far received would seem to indicate very strongly that there is no appreciable loss, and that, on the other hand, it does not pay any bee-keeper, when running for extracted honey, to let the queen have full range of the hive, supers and all.

Thus far the short splints—that is, those that do not reach to the bottom of the foundation—have given a good account of themselves. While W. Z. Hutchinson says there will be no sag if *medium brood* foundation is secured by four horizontal wires drawn taut, the facts remain that a light brood is considerably cheaper than the medium-brood sheet. Under some conditions the light-weight will buckle when the wires are drawn taut. If short splints and *light* brood foundation can be made to work satisfactorily they would effect an economy all around. We hope to get further reports on the use of splints, long or short.—ED.]

## A STUDY OF NATURAL HONEY-COMB.

BY DR. C. C. MILLER.

Comb foundation is in such general use nowadays that it would be nothing strange to find bee-keepers who have never seen a frame of entirely natural comb. I have been making a study of some specimens—a dozen in number—that were built entirely at the sweet will of the bees, not even the least starter being in the case. They range in size from a piece of a few square inches to nearly a frameful.

### POSITION OF CELLS.

Looking at brood foundation that I have, I find the cells placed with the angle at top and bottom.

In super foundation the angle is at each side, one of the cell-walls lying horizontally at the top and another at the bottom. I don't know why the two kinds differ.

The bees seem to copy after the first plan. Not very strictly, however. In only one case can the row of cells be said to be really in a horizontal row. In another specimen the row descends half an inch in about a foot. In the other cases the variation from the strict horizontal is still greater.

The cells run in a fairly straight row except in one frame where the line is somewhat wavy, apparently because there were four initial points of beginning, and the four parts were afterward joined together.

### SIZE OF CELLS.

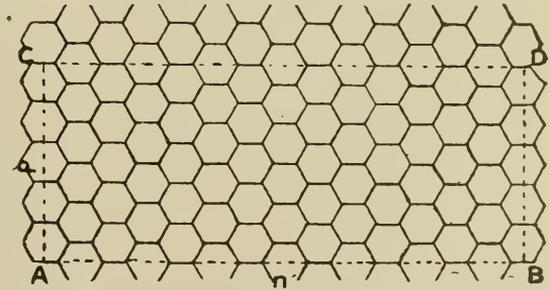

It is a common thing to say, "Worker-cells measure 5 to the inch, and there are, consequently, 25 cells on one side to the square inch." Neither of these statements is always true if we speak with any degree of accuracy. There are not always exactly 5 cells to the inch; and if there were, there would be, not 25, but  $25\frac{1}{2}$  cells to the square inch. See Cheshire, Vol. I., page 176—that is, if the cells were exact hexagons. The trouble is that they vary from this quite a little. On one piece of comb, measured horizontally, the average diameter of a cell was .201087 of an inch; in one of the diagonal directions it was .19853, and in the other .20357, the total average diameter being .201062 of an inch.

Upon reading those figures some one may think that I must have had some very nice instruments with which to take measurements. I had nothing but a common pocket-rule, and after I tell you how I did it you will see that a schoolboy could easily do the same.

Suppose I want to measure the diameter of a cell. Laying the rule upon it, and measuring merely that one cell, I could only say it was somewhere between  $\frac{3}{8}$  and  $\frac{1}{4}$  of an inch—not very exact. But if I measure 10 cells, and then divide by 10, I can come about ten times as near the exact measurement. The larger the number of cells I take in my measurement, the nearer I can come to exactness. Well, here's the way I do. I lay the rule upon the comb, with one end of the rule exactly corresponding with one of the cell-walls. Then I look along the rule till I see some notch which corresponds with some cell-wall. Then I count the number of cells in the given distance, divide the number of inches by the number of cells, and that gives the diameter of a cell. For instance, I find a notch of the rule at a cell-wall  $9\frac{1}{4}$  inches from the end of the rule. I count the cells, and find there are 46. I divide  $9\frac{1}{4}$  by 46, and I have .201087 of an inch as the diameter of one cell. Easy, isn't it?

But after I have the diameter of a cell it's just a little bit of bother to figure the area of the hexagon, especially as its three diameters are not all alike. A beautifully simple way of measuring the surface of a comb is given by A. Berchon, *L'Apiculteur*, p. 228.

Take the parallelogram ABCD. The line AC passes through the middle of 5 cells. Next to this vertical row of cells is another row of 4 cells, with a half-cell at top and a half-cell at bottom, making 5 cells in the row. So there are 5 cells in each vertical row in the parallelogram. The line AB passes alternately through the middle of a cell, co-

incides with a cell-wall, then through the middle of another cell, and so on. Each end of the line stops in the middle of a cell-wall; and if you put together the two half-cells at each end, the line measures 14 cells. There being thus 5 cells in each vertical row, and 14 in each horizontal row, there must be  $5 \times 14 = 70$  cells in the parallelogram.

Instead of measuring from the center of one cell-wall to the center of another cell-wall I find it more exact to let the line AB begin at an angle of a cell and end at the corresponding angle in another cell.

It may be worth while to notice that the figure, copied from *L'Apiculteur*, has the cells running the wrong way, a side of a cell being at top and bottom of each cell, whereas it should be an angle.

In one piece of comb, measured horizontally, there were 42 cells in  $8\frac{1}{2}$  inches, and measured vertically there were 38 cells in  $6\frac{1}{8}$  inches. Multiply 42 by 38, and  $8\frac{1}{2}$  by  $6\frac{1}{8}$ , then divide the former product by the latter, and you have 28.076 cells to the square inch in that piece of comb. In another comb there were 26.54 cells to the square inch—quite a difference in the two combs. T. W. Cowan (*The Honey-bee*, 181), took 36 measurements, and found the diameter of a cell to range from .186 of an inch to .211. That's a much greater variation than in the two combs I have mentioned; but then, he made more measurements.

In a sheet of brood foundation I find 26.62 cells to the square inch. That's about the same as my sample with the larger cells; but it has smaller cells than some that Mr. Cowan found in natural comb. That shows it would be feasible to have foundation with larger cells, thus working toward a larger bee, if a larger bee would get more honey. Of that I have some doubt.

Marengo, Ill.

## THE PRACTICAL TREATMENT OF AMERICAN AND EUROPEAN FOUL BROOD.

### Some Things we Know and do Not Know about these Diseases.

BY DR. E. F. PHILLIPS.

Read at the National Bee-keepers' Association Convention, Sioux City, Iowa, Sept. 22, 23, 1909.

The subject which has been assigned to me at this time is one of the most important now before American bee-keepers; and, unfortunately, it is not very well understood by any one. Toward the end of devising proper treatment, all investigations of the cause and characteristics of bee diseases must bend if they are to be of any value to the practical bee-keeper. However much the bee-keeper may be interested in the bacteriological findings in a bee disease, these things are of less importance in his practical work; but he wants and needs careful, reliable work on treatment.

The bacteriological investigations are very important, but I shall not dwell on this point. It is, perhaps, enough to say that, until we know the cause of a disease, and can make a detailed study of that cause, we can not know just what we are fighting.

In finding methods of treatment, there are two possible ways to proceed. By repeated trials of various manipulations the practical bee-keeper may, by chance, hit on something which enables him to save his property from destruction. He may make such a lucky find without any knowledge as to what has caused the disease. It was in this way that Schirach, in the eighteenth century, found

the shaking treatment for foul brood, and since then this same treatment has been used extensively. The Schirach treatment, or, as we now call it, the shaking treatment, enables us to prevent the brood diseases from destroying our bees, and it certainly is satisfactory in the majority of cases.

The other way of investigating treatments is to find the cause of the disorder, study its characteristics, and plan manipulation in the light of knowledge gained in that way. This method of procedure, while probably the more logical way, is open to the minority; but all can take the results obtained and utilize them without any great knowledge of bacteriological technique. But such work is slow. I fear that many bee-keepers wonder why the Bureau of Entomology is not able in a short time to make positive statements concerning the causes of disease, particularly European foul brood. To tell why would be a somewhat lengthy task; but let me simply point out that, in all diseases of animals so far studied, accurate results have been obtained only by years of work, and no problem in bacteriology is an easy one. It took years to establish the cause of American foul brood, and there is still much to learn. The bee-keeping public has been victimized by too many hasty workers who jump at results on insufficient data, and we do not care to be in that class.

To illustrate the great desirability of first getting the cause, let me cite some recommended manipulations. Because carbolic acid is used quite generally as a disinfectant, it has been repeatedly recommended that a 2 per cent to 5 per cent carbolic-acid solution be used to disinfect hives in which infected colonies had lived. This was done without a knowledge of the cause of either disease; and in the case of American foul brood of which we now know the cause it is certain that a 5 per cent carbolic-acid solution will not destroy the spores of *Bacillus larvæ* in the short time taken to wash out a hive. In the case of European foul brood, of which we do not yet know the cause, we are unable to say whether the carbolic acid acts as a disinfectant or not.

In a similar manner, without knowing the cause of either disease, various authors have recommended the feeding of carbolic acid, naphthole beta, salicylic acid, and similar drugs in sugar syrup to diseased colonies. While, as suggested previously, it is possible to stumble on a method of treatment by promiscuous experimentation, we should not take these recommendations too seriously until more is known about the disease. Such recommendations are largely confined to European authors; for American bee-keepers, from sad experience, have learned to put little faith in these treatments.

It has also been recommended that various antiseptics be placed in the hive to ward off disease. One European writer, posing as the omniscient guide of the bee-keeping world, writes in a recent edition of one of his books as follows:

There are certain antiseptics such as carbolic acid,

phenyle (or creolin), izal, eucalyptus, camphor, naphthaline, etc., which evaporate at the ordinary temperature of the hive, and whose vapors, while not actually killing the bacilli, arrest their increase or growth.

When it is remembered that this is apparently recommended without any knowledge as to the cause of any brood disease, it will not be taken seriously. Surely no American bee-keeper would entertain any hope from such a treatment.

It is wise at times to cast up accounts to see where we stand. Let us look over the field of bee-disease treatment to see what we know and do not know.

We know from the experience of hundreds of bee-keepers for years past that the shaking treatment will enable the bee-keeper to keep either disease under control so that he can remain in the business and make money out of it, if the seasons permit. This treatment consists of removing all combs, honey, pollen, and brood from the colony and putting the bees on foundation, compelling them to replace their comb, rear new brood, and gather new stores. By this means the diseased material is removed, and the contaminated honey and pollen which we consider as the carrying agents are no longer available to feed to the brood. We do not know what becomes of bacteria which may be carried over in the honey in their honey-stomachs, or possibly even on the outside of their bodies. We do not know when it is safe to use full sheets of foundation and when we should use only starters. There are many other points variously surmised which are not yet settled, and we must content ourselves with the fact that, if a diseased colony is shaken from its combs to a clean hive on starters of foundation, the disease rarely reappears. Starters of foundation are here specified, largely because reports would indicate a larger percentage of successes when they are used. If all worker comb is desired, the bees may be given full sheets of foundation later.

We do not yet know just when or how it is best to shake in order to meet with the least financial loss, and this is one point which must be thoroughly investigated. Ten frames of Langstroth size will probably contain, on an average, four pounds of wax; and to shake the bees so that they will secrete this wax with the least consumption of time and stores is a problem of great importance. Probably a more important point is to devise a way by which the bee-keeper can get out of the combs all the wax in them. Our present methods of wax extraction are exceedingly crude, and we are annually losing a great deal of wax by the use of the wax-presses now commonly employed.

We do not know whether it is always necessary to disinfect the hive or not; but to be on the safe side we should continue to do it until we know that it is not necessary. Since chemical disinfectants do not promise any results for American foul brood, and since we do not know the cause of European foul brood, we can be sure of complete disinfection by burning out the hives. If this is

done carefully it does not injure the hive. In the field work of the Bureau of Entomology a blue-flame torch such as is used in removing paints has been found very satisfactory.

We do not know of any antiseptic which can be fed in syrup or given in any other manner which will cure the disease. Neither do we know of any method by which combs can be disinfected by fumigation or otherwise to insure success. Until careful bacteriological work has demonstrated the value of any such method it would be folly to put any reliance in it. Furthermore the experience of most American bee-keepers up to the present has shown that antiseptic feedings and fumigations which have been tried are not of the value attributed to them. It would, therefore, be unwise to recommend them.

The logical practical treatment for both of the diseases under discussion would, therefore, appear to be the shaking method. Until something better is devised, this is the only treatment which we can recommend. When our knowledge of the causes of the two diseases is more complete, it is to be hoped that we can find something better. It is also to be hoped that the present weak points in the shaking treatment may be strengthened by work which will give us information whereby we can decrease the expense of shaking. The main conclusion which we can draw from a study of treatment is that there is still much to learn.

So far I have discussed the subject of control from the standpoint of the individual bee-keeper. We have learned, however, that individual action is not enough, and that co-operation and outside aid are the essential points in a rational control of foul brood. Although this portion of the subject of disease work is not specifically assigned to me, I shall ask your indulgence for a few moments longer on some phases of this problem which occur to me as a result of some recent experiments of the Bureau of Entomology.

The work of the various States in providing inspection of apiaries is of great value to the bee-keeping industry, and an earnest effort should be made to have proper laws passed where they are needed. In several States such movements are now on foot. When such laws are passed, however, we can not afford to believe that the problem is settled. It has only begun, and the State inspector can not be expected to do all that remains to be done.

The element of the work in controlling disease which will require the most labor is the educational feature. It is really remarkable, after all that has been written, how many bee-keepers do not know that there are any diseases of the bee.

The first step in this work is to learn just where the diseases exist. This phase of disease work has been neglected in this country, and no concerted effort has been made to establish the necessary facts. During the summer just closing, the Bureau of Entomology made a greater effort to locate diseases; and in all, we have examined nearly

a thousand samples to get the data desired. We are not yet prepared to give our results. In doing this work we are compelled to make it a rule never to be sure whether disease exists in a given locality until a sample of diseased brood has been obtained. Furthermore, all samples were examined bacteriologically to be sure of no error in diagnosis. In the case of European foul brood this is particularly necessary, for the symptoms are not constant enough to be sure of a sample after it has been away from the hive for a time. Many reports of disease turn out to be unreliable, and this matter is too important for any suspicions to be accepted as facts. While the sending-in of these samples of various persons interested is much appreciated, it has seemed rather strange that some men who were in a position to help us materially with this enormous task have not responded as we might have wished. There may be some bee-keepers who do not want it known that they have disease in their apiaries, and, therefore, are opposed to work on distribution. It is no disgrace to have disease break out in an apiary. The only condition under which a bee-keeper may be considered remiss is when he does not treat his diseased colonies. Any man who hides disease and tries to give the impression that his bees are healthy when they are not is, to say the least, no friend to other bee-keepers. In some States he is legally worse than that.

After the distribution is learned, the next step is to get in touch with every bee-keeper in the territory where diseases exist. This is not easy. During the past summer the Bureau of Entomology has sent out something over 10,000 circulars to postmasters, asking each one to give the names of bee-keepers in his vicinity. All of the returns have not yet been received, but each report will probably average five names. The same plan could be used for a request from a government department for all the postoffices in the United States (over 60,000 in number), if necessary; but our very limited office force will not permit it. In some parts of the country we have been able to get extensive lists of bee-keepers from other sources.

After the names of bee-keepers are received, the next step should be to send out a notice to each one living in a county where either disease exists, advising him of that fact, and sending a circular on the subject so that he can become familiar with the symptoms and treatment of the disease. We have not been able as yet to do this in many cases, but hope to continue the work in the future.

I have briefly outlined this scheme, not to advertise what the Bureau of Entomology aims to do nor to make elaborate promises, but merely to indicate the fact that, if diseases are to be controlled, it will take work to bring it about. To sit by and expect an inspection law to wipe out disease is not the part of wisdom. It has never done so yet.

Nor have I indicated all that must be done. I should be very much pleased, however, if by this outline I could induce each person

interested to do his share for the furtherance of the industry. The Bureau of Entomology will continue to do what it can with the present limited funds, but it would be just as unwise to leave too much to us as it is to expect too much of an inspector.

Washington, D. C.

## CASCARA AS A HONEY-PLANT.

### A Good Yielder in Sonora, Cal.

BY A. D. HEROLD.

The inquiry on page 677, Nov. 1, and your query regarding cascara sagrada as a honey-plant, have come to my notice. Cascara is, I may say, our main honey-plant in this locality. It is in full bloom about 20 days after apple-blossoms are gone, and lasts 25 days on an average; yet there are stray bushes near ditches or cultivated ground which send out new shoots of bloom, and these are visited by the bees until late in September or October.

I have sent you this day a sample of the extracted, which is, I should say, 95 per cent pure cascara. It is blended with spring flowers and grasses, and out with holly, so it is hard to get the full crop of pure cascara. However, we get more honey from cascara than from any other one plant in this vicinity. It is so dark as a comb honey that it is a poor seller to those who go on looks alone. We prefer it on our table to any other honey. I have customers who will take no other. It is not purgative, but one of the best remedies for chronic constipation known. I have never known any of the pure article to granulate under any conditions. Inclosed with the honey are some of the seed and leaves. It is not an evergreen, but it is as green as the bay-tree all winter, and until late in the spring. The new buds push the leaves off, and at the opening of bloom it is nearly free from leaves.

I think it would stand the winters of Ohio if protected while small. It is a rapid grower, a most prolific bloomer, producing both honey and pollen. It is just fun to see the bees working on it, the flowers are so thickly set together—shallow, and accessible to bees to work on in their great haste. In the evening they file out of their hives with pollen on their legs, eager for another load before night overtakes them—something I have never noticed when they worked on any other flora.

I think it is a great honey, and could be sold at a higher figure if properly advertised. I have had customers send it to their invalid friends in Ohio, Indiana, the Dakotas, and Pennsylvania. I had 1000 lbs. of extracted and 300 lbs. of comb from this plant, from 44 colonies, spring count.

Sonora, Cal., Nov. 8.

[If cascara honey can be used as a medicine the facts ought to be known for the benefit of the few who have need of it. It ought to command a big price.—ED.]

## HEADS OF GRAIN FROM DIFFERENT FIELDS

### THE NEBRASKA STATE FAIR.

The apiarian exhibit at the Nebraska State Fair this year was of unusual excellence and largely increased size, taxing the limits of the building assigned for that purpose. Seven exhibitors, representing every section of the State, crowded the shelves to the limit, and a petition has gone to the management for increased space for the coming year, as well as for premiums in new classes, which will, no doubt, be forthcoming.

The substantial special premiums offered by The A. I. Root Co. and others have stimulated competition, and the two splendid silver trophy cups given by the State fair management and the Nebraska State Beekeepers' Association, added materially to the attractiveness of the exhibit, and the zest of the competitors.

One of the largest individual exhibits was that of the Trester Supply Co., of Lincoln, the oldest exhibitors at this fair. This splendid exhibit, in point of size and general excellence, probably the best they have ever shown, reflects great credit on this concern, and won the special silver trophy cup offered by the management of the fair for general display.

The most interesting display from the point of general interest was that of Frank G. Odell, of Lincoln, representing Roselawn Apiaries. Mr. Odell showed a collection of four hundred mounted specimens of honey-producing plants, the largest ever shown at any State Fair. This list will be published by the Secretary of the State Board of Agriculture. It won the first premium in cash as well as the special first premium offered by the *Bee-keepers' Review*. Mr. Odell showed the prize-winning collection of bees and queens, securing first in all competitions, and three specials offered by The A. I. Root Co. for bees, with his showing of fifteen observatory hives and five different races of bees.

The display of beeswax and comb-honey designs was especially interesting, this concern showing a model of the Wright aeroplane made of beeswax, and the words "Roselawn" in comb honey, both of which easily won first premiums. Mr. Odell won all specials for which he entered, including a Root ball-bearing extractor, a Hatch wax-press, a copy of the A B C in German, and five pounds of Weed process foundation offered by The A. I. Root Co., besides the largest individual winnings of cash premiums of any exhibitor in the department.

This exhibitor also gave two lectures daily on economic apiculture, with demonstrations with live bees in a cage, being especially employed by the management of the fair for that purpose. These lectures were attended by great crowds who listened eagerly to the attractive side of bee-keeping as presented by the lecturer.

A special honorary diploma was awarded by the fair management to Mr. Odell as expressive of their appreciation of his labors.

Lincoln, Neb.

G. M. PLUMB.

### SHALL WE SHAKE THE QUEEN IN PRACTICING "SHOOK SWARMING"?

In the A B C and X Y Z the Doolittle method of preventing swarming is treated on p. 416, but I do not see where any thing is said as to how the queen is transferred from the old hive to the new unless it is intended to "shake" her off with the rest of the bees and allow her to find her way into the new hive with the others; but in all I have heretofore seen relative to the handling of queens there is so much caution advised, for fear of doing her some injury, that this seems like rather rough treatment for so delicate a character.

Greenville, Miss., Dec. 9.

N. B. JOHNSTON.

[When we speak of shaken or "shook" swarms we seldom make any reference to the queen, leaving the matter of how the queen gets into the hive at the option of the apiarist. Probably there would not be one time in three or four hundred colonies shaken where the queen would be lost if the bees were shaken in front of the entrance without paying any attention to the queen. There is a possibility, however, that she might be injured if she were in the height of her egg-laying; but as she will fall, in almost every case, with a bunch of bees she would receive no harm. As a general practice we might say it would be advisable to pull out the first two or three frames, and, after the queen is located, set the frame she is on to one side; shake all the other frames in front of the entrance

then, last of all, take the queen off the frame and place her among the bees that are running in, after which shake the frame. But if there is a large mass of bees on the ground in front of the hive it would do no harm to shake bees, queen, and all.

On the other hand, there is a slight objection to the apiarist picking up the queen and handling her at all. The contact of the human fingers sometimes changes her body odor to an extent that will cause the bees to attack her. It would, therefore, be our candid opinion that there would be no more loss in shaking without paying any attention to where the queen was in the hive than if we take the time to hunt her up, pick her off the comb, and let her run in with the bees.—ED.]

### AN APIARY DESTROYED BY FLOOD.

One of the worst storms in the history of this section occurred Sept. 20, lasting more than 24 hours. It did great damage to property and life. We have a large body of water in our front, the Mississippi River, and a big lake at our rear. The wind backed up the lake water, placing mine water, and submerging land that has heretofore been free from overflow. One of my apiaries of 75 or 80 hives, in prime condition for wintering, has been completely destroyed. The water is yet on the land; and as there are snakes in and around, it is any thing but pleasant to work gathering up the boxes and combs.

I have a few hives at my home, mostly nuclei, and I doubt if I can carry them through winter. The apiary that was lost gave me all the extracted I got this year, so I have nothing to look to next year. It took 20 to 25 years to build up and 24 hours to destroy. That knocks the grit out of the best of us.

New Orleans, La., Oct. 11.

G. P. HOWELL.

[We were very sorry to learn of your loss through flood; but we would draw your attention to the fact that you can make very rapid increase with these combs and hives, and you will probably find that the combs themselves are not very badly damaged. It was Mr. Adam Grimm, who, along in the early 60's, made enough money out of his bees to establish a bank. When asked what he would do if he would lose all of his bees during the winter he said, "I would show you how quickly I could get them back again with all these drawn combs and hives." The fact of the matter is, one can make a very rapid increase when he has the full equipment, and this you undoubtedly have. If the combs happen to be filled with mud or dirt, take a hose and wash them out with a spray of water as best you can, then give them to the bees as fast as they can take them.—ED.]

### ABSORBENT CUSHIONS BEST FOR DAMP WINTERS; WHY BEES CLUSTER TOWARD-THE FRONT OF THE HIVE.

On page 654, Nov. 1, the editor refers to the difference of experiences and opinions respecting the top covering for outside-wintering bees, and seems inclined toward tight or sealed covers. Always having wintered my bees outside, it has been my practice to use porous packing over the frames, and with most excellent results so far as the packing is concerned, excepting in a single instance, if I remember rightly. The material used has been dry planer shavings. The exception was the use of a sack of sawdust about 6 inches thick, very closely packed over one of the strongest colonies. They came out in the spring in very bad condition because of moisture in the hive. I thought that possibly the cover might have leaked, but found this not the case. The under side of the sack was wet as well as the hive; hence the conclusion that it was the closeness of the packing.

It occurs to me that, in a dry atmosphere, bees might be wintered safely outside under a sealed cover; but in a winter of very much moisture a porous covering of proper material, such as planer shavings or ground cork, which might be better, would, it seems to me, be the proper material to use. There is another factor to be reckoned with in my case, perhaps. The covers are four to six inches above the packing, thus leaving a dead-air space above the cushion, which I deem very desirable in outside wintering.

In reply to a correspondent who asks why bees cluster in the front part of the hive, like Dr. Miller, you frankly say, "I don't know." Permit me to suggest a reason for bees doing this. During the summer time, when brood-rearing is going on, there is a tendency to put the brood forward and the honey at the back and above. This is partly owing to the fact, I think, that the wind blowing into the hive in early spring when brood-rearing commences strikes across the hive under the frames, then rises, making it more dif-

difficult to maintain an even temperature than at the front, and this may account for bees doing the same thing during cold weather. Hives being placed fronting either east or south, the warmth of the sun has likely something to do in attracting the cluster in the winter toward the front of the hive, especially in the single-walled hive. WM. M. WHITNEY.

Batavia, Ill., Nov. 17.

#### SOME OLD SECTIONAL BEE-HIVES OF A CENTURY AGO.

In looking over some of my old books I found an encyclopedia, published in 1821. It has about 15 pages devoted to bees and hives, and is quite interesting. There is a cut of a divisible hive very much like those of to-day except in shape, being square, with fixed straight bars instead of movable frames. It tells how to make artificial swarms with this hive, very much as we do to-day, and quite a lot of queer ideas in regard to bees. F. T. BROOKE.

Staunton, Va., Nov. 22.

[The article to which you refer is possibly a description of what is known as the Nadir or Eke hives that were used in Europe some hundred years ago, and, in fact, are still in use. This whole system has been written up in our columns at numerous times. If you will read over the article carefully you will probably find either one of the names referred to. That old system was very similar in many respects to the divisible-brood-chamber hive that is in use to-day, with this difference, that the combs in each section were immovable; but the manner of handling the sections was somewhat similar to that used with the present hives.

By turning to page 247 of the latest edition of our A B C and X Y Z of Bee Culture you will find also a description of what is known as the Stewarton hive of 1819. This had bars for supporting the combs with glass strips between. It was also described in Cheshire. It is possible that the Stewarton hive is the one that is described. It is eight-sided, split up in sections.—ED.]

#### BEES IN WASHINGTON COULD WORK EVERY DAY IN THE SEASON IF THE WEATHER CONDITIONS WERE MORE SUITABLE.

We are located in the southern part of Washington, in the foothills of the Cascades, on the western slope. It is an ideal place for bees so far as honey-producing plants are concerned; but, of course, the weather conditions are not always ideal. We have a great deal of rain here, and last season there was too much cool and cloudy weather during the time for a honey-flow, so that the nectar was not properly developed in the flowers, and consequently the crop was almost a failure. The honey-bearing flowers come on in this order: Willow, wine maple, which bears an abundance of nectar; wild blackberry, wild vetch, salad berry (a good honey-bearer in its season); then the famous fireweed. So you see we would have a continuous honey-flow from April 1st until Sept. 1st provided the weather conditions were right.

The fireweed honey is delicious, very white, and of fine flavor. It ranks first in market here, and I believe it would the world over.

During the season of 1908 we had 40 hives of bees,

and sold \$700 worth of honey. At the present time we have 55 hives in fine condition for winter, and we are building great hopes for another season.

We do not put our hives in winter storage here. They do very well when left out in the open.

Brush Prairie, Wash., Nov. 20. MRS. D. N. BRACK.

#### DISPOSING OF LAYING WORKERS BY TEMPORARILY UNITING THE COLONY WITH A STRONG QUEEN-RIGHT COLONY.

On page 674 is given a quick way of ridding a hive of laying workers. For many years I have practiced a much quicker way. It rests on the assumption that a queen-right colony will not tolerate the presence of fertile workers. The hive to be treated is placed late in the evening quietly, and, if possible, without smoking, over a strong queen-right colony whose supers have been removed for this purpose. After the two colonies are thus united, the supers are replaced on top of all. Next morning the hives are separated, and, if thought best, made to exchange stands. Late in the evening of the same day the smoker is filled with sassafras chips, and a queen run in. In this temporary union the queen-right colony should always be the under hive for the safety of the queen.

Otterville, Mo., Nov. 18.

E. W. DIFENDORF.

#### GOOD PRICES SECURED BY SELLING HONEY EARLY.

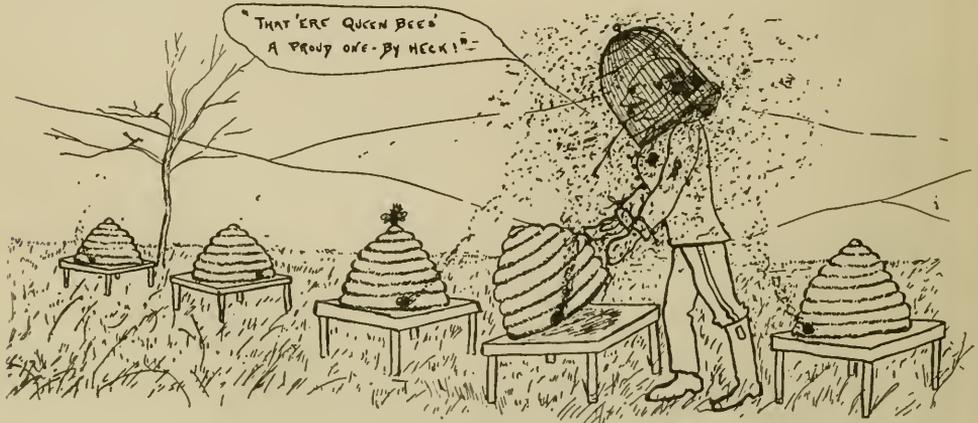

By getting my crop before the honey-eating public at an early date I have found that it pays well, for I get 17½ cents per section for all my comb honey, and \$2.00 per gallon for my extracted honey in glasses. The demand is heavy, for I sell direct to the consumers and not to the merchants.

The merchants in the grocery business are often to blame for poor sales, as they sometimes store fine comb honey in dark damp cellars, near pickled meats, fish, cheese, etc., and the customer complains about the bad flavor. I believe all producers should caution grocers against storing honey in the cellars and against handling it carelessly, as this accounts for so much breakage, and the honey comes in contact with dirt and dust. Chico, Cal. SYLVIUS J. MORRISON.

#### NEW YORK SERGEANT OF POLICE IN CARTOON.

Mr. E. R. Root:—Herewith find inclosed a cartoon of myself which I received from some unknown source, and which I consider clever enough to be reproduced in GLEANINGS. I am the son of Mr. N. D. West, bee-inspector of New York State, and you will remember me as the boy who showed you through his apiary when you were on a bicycle trip through Schoharie Co. in 1890. I was appointed a patrolman in New York by President Roosevelt when he was Police Commissioner here. I am now sergeant of mounted police, and continue the bee business on a small scale in New York. The cartoon is supposed to represent me in police uniform looking at my bees. You will note in the cartoon that the queen wears a crown, and that I, farmerlike, have a straw in my mouth.

EDWIN H. WEST.

## WHAT STYLE OF HIVE TO ADOPT.

1. Would there be any advantage in locating an apiary on a hill from which one could see the surrounding country for several miles?
2. What make of hive would you recommend in the out-apiary, for extracted honey?
3. The most successful bee-keeper I know uses the eight-frame hives, and tiers them up. I have started that way. Would you advise me to change, as I intend to go into the business more extensively?
4. Which do you think better—deep or shallow extracting-frames?
5. On page 695 J. E. Hand says, "raise up the whole hive and place a super of empty combs under it." Why wouldn't it be better to put this super of empty combs on top of the brood-chamber instead of under it, as the queen's natural instinct is to go up?

In this section the first surplus honey comes from basswood, about July 10, and we have a good fall flow. Elk River, Minn., Nov. 23. FRANK MORGAN.

[1. In some localities, we believe it is a distinct advantage to have an apiary located on a sidehill commanding a view of the valley and the hills beyond. The late E. W. Alexander claimed that one reason why he was able to have 800 or 900 hives in one locality was because his bees could see the white patches of buckwheat several miles away. He believed that bees have a sort of telescopic vision, and that, when they can see the white patches, they will go further for honey than they would were the view shut off by buildings or shrubbery or trees. Of course, one might argue that the bees could fly high enough to look over every thing. But they will not do so if they can avoid it. Bees going to and coming from the fields always fly as low as possible, rising only enough to clear obstructions.

2. That depends on the man and conditions. Generally speaking we would advise the ten-frame hive rather than the eight-frame for extracting, for the average farmer or bee-keeper. If one has made a special study of the sectional or double-brood-chamber hive we would advise the shallow extracting-super. J. E. Hand, Louis H. Scholl, and some others consider this the best for extracting. The main advantage is that the storage room can be more gradually increased.

3. If you have started with the eight-frame hive we would advise you to stick to it. The gain would not be enough to warrant the change.

5. This question is referred to J. E. Hand for reply.—E.D.]

## DETERMINING WHETHER A COLONY IS QUEENLESS BY THE PITCH OF THE HUM OF THE BEES; LOCATING THE FRAME CONTAINING THE QUEEN BY SOUND.

On page 192, April 1, is a quotation from Mr. F. J. Miller on finding the queen by the lowness of pitch of the note made by the bees. This is a very interesting thing; but it requires an educated ear. As I have been a violin-player for something over 20 years my ear is very correct. My experiments this summer would indicate that not only will this low-toned hum tell where the queen is, but whether the colony has a laying queen or not. I could not make a nucleus formed with queen-cells produce this tone until the queen had begun to lay, and I have not yet failed to make a queen-right colony produce it. If you will blow a little smoke in at the entrance, and tap the side of the hive three or four times lightly, then take off the cover as quickly and quietly as possible, listen carefully, and note the point where this low tone starts, you will find the queen right at that point. It is seldom that one can locate this point closer than the space between two frames; but it has been my experience that, if these two frames are taken out, the queen is pretty sure to be on one of them. It seems to me that if this method of telling whether there is a laying queen or not will always work, it is a good one—no opening of the hive, no taking-out of frames for examination. Just smoke the entrance a little, and tap the side. If they sing low, all right. If they just buzz they need attention. P. W. RICHARDS.

Mast Yard, N. H., Nov. 6.

[It is well known that a queenless colony, when disturbed, will give off a roar or hum of distress. Some colonies not queenless, under a state of excitement will give off the same noise. As a rule, any queen-right colony should give off a very low and contented hum, but we doubt whether the average bee-keeper, at least, would be able to determine the approximate location of the queen by the method you describe; but it is a fact that bees will *sometimes* indicate her position by their general behavior; but when the hive is

opened, and a little smoke is blown over the frame, the natural status of the colony is so changed that ordinarily we can not tell, for the moment at least, in what part of the hive the queen is.—E.D.]

## FOLDED PAPER INSTEAD OF CHAFF TRAY.

I see that you are on the right track on wintering your bees on summer stands with the deep telescope cover. But you do not need that tray on top, or at least I do not out here. I have wintered my bees the last ten years with a deep telescope cover with paper laid on top of the super cover (sealed down), the paper reaching down on the sides and ends, some with old carpet on, but mostly newspapers. I have not lost a single colony.

The space under the frames is  $\frac{3}{4}$  inch. I take a strip or block that reaches clear across the entrance, and cut out a notch  $\frac{3}{8} \times 6$  inches, and lay that in front, leaving the entrance  $\frac{3}{8} \times 6$  in. Another thing, I have never had an entrance clog with dead bees nor had to clean dead bees out; but in the spring I lift the hives off the bottom-boards and clean the cuttings of the comb out. This is the best way and the only way to winter bees. H. MANSPERGER.

Lewistown, Mo., Nov. 22.

## TO PREVENT BEES FROM FLYING OUT OF THE ALEXANDER FEEDERS WHEN THE SYRUP IS Poured IN.

In your issue for Oct. 1, p. 611, Mr. H. A. Moody gives his plan for keeping bees from rushing out when using the Alexander feeder. My plan is this: Bore a  $\frac{3}{4}$ -inch hole about the middle of the feeder-cover. Lay a small block over the hole and drive a small nail through one corner of the block into the cover to make a hinge for the block to swing on. Provide a funnel to fit the hole, and a cup that holds the amount you wish to feed. With the end of the funnel push the block around out of the way, sliding the funnel over and into the hole as you do so, and pour in the feed. Not a bee need escape.

Beresford, Fla., Nov. 4.

C. S. GAILBREATH.

## BEE-SHED MADE OF Baled HAY.

Would you please advise me whether a bee-house laid up of baled hay would be warm enough in this locality to winter bees successfully?

Forest City, Iowa, Dec. 3.

RUFUS R. WAGNER.

[We have had no experience with bee-houses built of baled hay, and we do not feel competent to advise in regard to the matter. It would seem, however, that such a building should be warm enough, providing the cracks between the bales, etc., could be kept covered up.—E.D.]

## THE FLOUR METHOD OF INTRODUCING A FAILURE.

I have tried the flour method of introducing queens time and again, and not in a single instance have I been successful. I could not decide to give the plan up, as I realized that, if I could but learn to manipulate it successfully, it would be of great value to me as I intend to install a great many queens next spring. I should like very much to know what Dr. C. C. Miller thinks of the plan. J. B. MARSHALL.

Big Bend, La., Nov. 25.

## THE FLOUR METHOD OF INTRODUCING QUEENS NOT A SUCCESS.

I tried this plan of introducing, but without success. The bees and queen get busy with the flour, so there is no notice taken of the new queen at first; but in every case as soon as they got rid of the flour they balled the queen.

Merino, Col., Nov. 22.

T. J. LANDRUM.

## HONEY FROSTING.

Here is a good plan to make honey more suitable for those who can not eat it ordinarily. Boil some comb honey, or, better, extracted, until it is crisp when cooled. Dip in and well cover any plain or fancy crackers, and when cool they are fit to serve.

Seabright, N. J.

HERBERT S. HALE.

## SEALED COVERS UNDER GROUND CORK.

I use sealed covers with a super on top filled with ground cork, such as grapes are shipped in from Italy, etc. Dampness in the hive is thus reduced to a minimum, and the bees winter well.

Philadelphia, Pa., March 28.

R. P. ZEBLEY.

# OUR HOMES

By A. I. Root

Every man that striveth for the mastery is temperate in all things.—1. COR. 9:25.

WHAT SHALL WE EAT TO "KEEP WELL AND LIVE LONG"?

It rejoices my heart just now to see how the pages of our magazines and other periodicals are gladly thrown open to let Horace Fletcher tell us of his discoveries in the way of simple diet. Much good is certainly coming from it. The trouble is, that so many are unwilling to give up the old way and adopt the new. But a wave of reform is fast spreading over the whole wide world; the need of reform seems to be more appreciated just now than ever before since the world began. Somebody has suggested that, a few years ago, the flag that waves over the United States was saved from being trampled in the dust by the patriotism and self-sacrifice of the North; but in God's wonderful providence it seems now as if the tables were being turned, and that the *South* were now about to take the lead and teach the North some wholesome lessons. The North, years ago, took the lead in abolishing slavery; but just now the South is, without doubt, taking the lead in abolishing, if not a greater evil, one just as great. The tyranny and dominion of strong drink and the liquor forces die so hard that it looks very much as if troops and soldiers would have to be called out to enforce our just and righteous laws. In Atlantic City we have recently had an illustration of this. Now, while it seems as if the influence of every man and woman, and perhaps of the children too, is needed to preserve and enforce our laws, it seems to be more and more evident every day that every man, woman, and *child* should be exhorted as never before to rule his own appetites and other low passions. May God be praised that President Taft had the grace and courage to decline to take a glass of mint julep that was prepared especially to give him a hospitable welcome. We are told that he smelled of the mint, and probably admired its aroma; but he set the glass down without even tasting the intoxicating beverage.

Now, the success of Fletcher's and Terry's teachings depends on self-control. When you have discovered that certain things disturb your digestion, let them alone, no matter how much the effort costs you. I am often tempted to taste of apples, grapes, and other fruit between meals; but I have learned by experience that bad results are sure to follow; but if I go and get a drink of nice cool boiled water, which I always keep on hand, the longing for fruit soon passes away. Of course, I can not prescribe for other people; but it is certainly very much better for myself to take nothing in my mouth but pure water except at meal time. In the same way, I am tempted, like other people, to have a piece of pie or dessert when it is offered me after I have already eaten as

much as is good for me. When you are visiting, and you have reason to think the good housewife has prepared a little something extra, perhaps because of your presence, it seems almost uncivil to refuse to taste pie, ice-cream, or other desserts; but I am sure it is best. My strength holds out ever so much better when I pleasantly tell the good friends who have invited me that I have made an excellent dinner, and have already partaken of all that is good for me. These things, as I have said, require the exercise of self-control over the appetite, and other things in the same way. Let your motto be, not what you *want* or *greatly desire*, but what is *best* for you. Let *duty*, not *inclination*, decide the matter. Terry has told us that it is sometimes necessary for him to exercise self-control in order to stick to his uncooked wheat when there are so many other things round about him in such profusion. But he got back his health and a robustness of mind and body beyond what falls to the lot of common mortals by exercising self-control, and eating that which he knows from past experience is best for his health. After he has for quite a period exercised this self-control he tells us that he enjoys the uncooked food more than he ever enjoyed eating any thing before in his life. I think he is recognizing, however, that no two of us require exactly the same kind of diet. Some of his followers are eating common wheat just as it grows on the farm; but they cook the wheat in a corn-popper or parch it slightly, then grind it in a little cheap mill, and eat it that way. For variety they sometimes add a small proportion of popcorn. And, by the way, I have found that popcorn is a very wholesome food, especially if it is put through a little mill, and then eaten with milk. Fletcher tells us that, when he performs his great athletic feats, he eats nothing but a cereal and milk, and a little lump of maple sugar. I am well satisfied that maple sugar is more wholesome than the refined sugars in common use. Fletcher says it does not make so much difference what cereal you use, providing it is thoroughly chewed. By the way, some people think that eating slowly means chewing slowly. Not so. Fletcher says that he chews just as fast as he can make his jaws go, especially when in a hurry. Get every thing into a liquid state, or semi-liquid, before swallowing it.\* If your

\*In the last issue of the *Practical Farmer*, Terry tells us more about that Quaker City mill No. 4 that they use to grind their graham flour and other things. The mill cost all together \$3.80. The address of the company is A. D. Straub & Co., 3739 Filbert St., Phila.

By the way, you are probably reading up about that terrible disease called "pellagra." Well, *McClure's Magazine* says it is caused principally by moldy corn that is used to make corn meal. Sometimes some millers purposely put in a little moldy corn to get it off their hands. They think the quantity is so small that nobody will notice it, and that it will do no harm. And it is well known that it is almost impossible to get genuine graham flour on the market. Millers and middlemen seem to think they can dump almost "any old thing" into graham flour, and it will be all right. The remedy for this terribly bad business is to get one of these little mills and make your own corn meal and graham flour from the best corn and wheat of your own selection.

teeth are poor, the little mills that you use in the home, described by Terry, are an excellent aid. He uses them for grinding nuts as well as wheat and other things. It is all right to assist the teeth in every way you can; and I think a little cooking—at least many times—not only assists the teeth, but renders the food more nourishing.

Fletcher differs from Terry in saying one may eat whatever the appetite calls for particularly. In other words, let nature decide, as far as you can conveniently, what she wants to make a balanced ration. Terry makes a balanced ration of wheat, fruit, and nuts; and, if I am correct, Fletcher, especially since his repeated visits at the Battle Creek sanitarium, is leaning toward an exclusively vegetable diet. Somebody has suggested that his directions, to take whatever the appetite craves most, might include beer and even whisky; but you all know that Fletcher never intended to say any thing of that kind.

Now, I want to bring in another one of my "discoveries;" but let me digress a little before I do it.

There is now a great craze to know how to feed poultry so as to get the most eggs; and most of us have discovered, I think, that a change of diet helps to make the biddies contented and happy, and, as a consequence, bring more eggs in exchange for the food provided. Let me suggest that you make an experiment. Teach your fowls to eat lettuce if they have not already learned to do so; and, finally, give them all they want, no matter if it does cost something; and if it does not immediately increase the number of eggs I shall be much mistaken. After they become a little tired of the lettuce, cook up some cull beans and mix them with bran middlings or meal so as to get them started on a bean diet. You will soon find that the beans, in a like manner, give an increase in the egg output. Then try lean meat or ground bones. Do not give them too much at once, but accustom them to the new diet gradually. This meat diet almost always produces a marked result; and all three of these different foods are equally beneficial in growing chickens. When I was on the island a large brood of chickens were chirping around as if they wanted something they did not have. I finally concluded they wanted animal food, and gave them all the fresh fish they would eat. They were just crazy for it; and after they had eaten enough the whole thirty or forty went and sat in a row on a log. Their natural craving was satisfied, and they were contented and happy; and since that time I have seen my chickens do the same thing here in Ohio. When they seem to be uneasy and dissatisfied, try different things. When you hit the spot you will see your chicks go and roost on the fence or on a log, in a long row, contented and happy. Nature has been satisfied. When they do this they will grow and keep well.

Now, I hope our vegetarian brothers and sisters will excuse me if I suggest that, so far as my experience goes, we "humans"

are much like the chickens. It looks to me as if there were times when growing children and elderly people need animal food just as the chickens do. There may be, however, some substitute that will answer equally well; my discovery comes in right here. Mrs. Root complains sometimes that I do not eat the things I have been calling for all along after she has got them all ready for me. For instance, for quite a time I thought that shredded biscuit was just the thing; and I was not satisfied unless I had it at every meal. Finally I "switched off" on to the Battle Creek graham crackers, and I almost lived on them. (It occurs to me right here that one of our children said to somebody a little time ago that I almost "lived on" apples, and if you were to see me eating a great plateful every evening when looking over my agricultural papers you might think that apples were the "chief part of my diet.") Well, after I had been on the graham crackers about so long I took a start on puffed wheat, and it was puffed wheat and nothing else, three times a day. After that I took a great fancy to hulled corn—you know I told you about the hulled corn. Well, all of these things did me good. The change did me good. It gave me new vigor, almost as well as new strength of body; but three or four weeks ago, in some way I did not hold out, either in mental or physical strength, and I have had an increased amount of mental work lately in order to prepare for my trip to Florida. Evidently, nature was admonishing me, just as she admonished the chickens, that *something* was lacking. I tried my Hamburg steak, and it helped me somewhat; but my vigor and enthusiasm did not hold out clear up to the next meal as I wanted them to do. Just then I saw a lot of nice chestnuts in a grocery, for "chestnut time" had come. They were 25 cents a quart; but even at that price the expense was nothing compared with what people pay for stuff in bottles at the drugstore. I have often explained that apples are my medicine, and I still consider them one of the very *best* medicines in the world. Well, I bought two quarts of these chestnuts and put them in a pan in the oven in order to "cremate" the "live things" that might be inside of some of them. They were left over a slow fire until they were just right. At supper time I said, "Sue, there has been some discussion as to what kind of food is the most delicious that God ever furnished to His children. I think now that I shall put roasted chestnuts at the very top of the list."

After a few days of having a good-sized handful of chestnuts at the close of every meal, I can add that not only were they the most delicious food I ever tasted, but they seem to be, in my case, a most strength-giving food. I dictate and answer my letters with more energy and zeal than I have before for many years; and I feel more like running a race with the boys, and climbing the ladders to get to the top of that great warehouse where they are just now putting on a cement roof after having put in two

floors below, entirely of cement, without a supporting timber in the whole structure, or any thing that can burn and let the building down in case a fire should start inside.

It looks to me just now as if the chestnuts were not only a substitute for the meat I have been in the habit of using, but perhaps better than meat—yes, a good deal better; and this comes exactly in line with what Terry has been trying to teach—that the various nuts that can now be purchased in the market may supply the elements that make up a balanced ration without using any meat at all. If you can enjoy them as much as I do you can certainly thank God for the nuts; and it looks as if there might be several reasons for so doing, instead of one.

Now, friends, there are fierce passions that assail every one of us—more fierce by far than the appetite for something to eat or drink; and, what is of equal importance (I do not know but I should say of *more* importance) we should be evenly balanced and well *spiritually* as well as physically. The loving Father has laid the responsibility on all of us to hold these passions in check; and we can not be at all worthy of being called a creation in his own image unless we do exercise this self-control. Sometimes we are inclined to think it is “pretty tough” to be obliged to put up with our environments when others have so many things, and seem to do as they please. But remember the promise, “He that is faithful in few things shall be made ruler over many things.” It may seem to you that your life is rather monotonous, and that you are having a hard time of it. But do not be in a hurry. Study God’s holy word; come to him often and tell him your troubles, and ask him to guide your footsteps, and you will surely have your reward.

---

## TEMPERANCE.

---

There are two particular things I am very much in sympathy with—the present war against the liquor-traffic and the speedy “expose” of all swindles and humbugs on an honest and unsuspecting public. Now let me explain that, while I am heart and soul in favor of prohibition, I am not at present a member of the political Prohibition party. God seems to have called *me*, at least just now, toward pushing and helping the Anti-saloon League. Nevertheless, I wish every one of you would send for a sample copy, if nothing more, of the *National Prohibitionist* (of Chicago) and see what it is doing to show up the outrageous humbugs and frauds of the liquor people of the present time. I wish especially you could all see the “cold-chiselled facts” furnished by the department at Washington, D. C., as given in the *Prohibitionist* of Nov. 25th. Editor Ferguson may not *always* be exactly right; but he is *tremendously* correct this time, and may God be praised that the manufacture of liquors is falling off.

## HIGH-PRESSURE GARDENING

By A. I. Root

---

THE WONDERBERRY, AGAIN; A LETTER FROM JOHN LEWIS CHILDS.

Mr. A. I. Root—I notice in your issue for Nov. 15 that you say editorially that the wonderberry was not created by Mr. Burbank, and that it was already known as the “garden huckleberry.” I do not suppose you wish to make any misstatements, and will, therefore, be glad to be corrected; and I would say that Mr. Burbank *did* create the wonderberry, which is a hybrid between two species of *Solanum*. I do not think anybody doubts that. It is entirely different from the garden huckleberry or the wild nightshade, which you must know if you have grown the two and compared them. It had never been grown anywhere before Mr. Burbank originated it, and I introduced it last year, notwithstanding all reports to the contrary.

I have run down every claim from any part of the country that has been made that the wonderberry was growing there wild or otherwise, and I found in every case that it was an entirely different plant.

My reputation as a seedsman is worth more than any thing I could make out of the wonderberry or a dozen novelties like it; and it is not idle talk when I tell you positively from my own knowledge that the wonderberry is a new, distinct, and very valuable fruit.

JOHN LEWIS CHILDS.

Floral Park, N. Y., Nov. 29, 1909.

We are certainly glad to get and give place to the above letter; but I would beg leave to suggest that this matter is not to be settled by Dr. Britton, the botanical gardens, nor even Dr. Galloway (of the Bureau of Plant Industry of the United States), but by the great public who have purchased seeds and grown the plants. In answer to our call, and that of the *Rural New-Yorker*, great numbers of reports have come in, and berries and plants have been mailed us grown from the seeds purchased of Childs. Now, please note. These berries and plants from the *wonderberry seeds* have produced, I might almost say, quite a *variety* of plants and *berries*—some blue, some black, some large, some small, etc., all the way from the wild nightshade to the garden huckleberry. See Galloway’s letter, already given in GLEANINGS, p. 585, Sept. 15. Childs says in his letter given above, “It has never been grown anywhere before;” but what does the great public say (through GLEANINGS and the *Rural*), from north, south, east, and west? Again, Childs says, “Burbank *originated* it,” and both Childs and Burbank advertised it as a *new thing*; but has this same great public agreed that it was *not known before*?

At least *some* of the seeds Childs sent out produced the old well-known garden huckleberry.

If the general verdict of the great public at large who have purchased seeds of the wonderberry of friend Childs is that they have found it a *new fruit* not known to them before, I humbly beg pardon of both Childs and Burbank.

I know how customary it is for seedsmen introducing novelties to exaggerate, and, perhaps, thoughtlessly misrepresent. May God help me that, after my past years of experience, I may be more careful in every way lest I use extravagant expressions.

# GLEANINGS IN BEE CULTURE

## EDITORIAL

By E. R. ROOT.

IN view of the fact that A. I. Root, in his Florida home, where he goes for rest and recreation, has no stenographer, all correspondence relating to bees and general business, and all other matter except that requiring his special attention, should be sent to the A. I. Root Co., at Medina. Mr. Root, Sr., has paid comparatively little attention to bees since his elder son, the writer, took practical editorial charge of the journal 24 years ago last December. While A. I. R. did not at that time drop all connection with apicultural writing he gradually let go; and now, and for many years back, all matters relating to bees and bee-keeping are taken care of by his sons. All matters relating to the Home talks and special agricultural subjects may be referred to Mr. Root at Bradentown, Florida; but the reader should remember that, owing to the lack of facilities for taking care of correspondence, his replies, if any, will have to be very brief or answered in GLEANINGS. It would be a physical impossibility for him to reply to all the kind friends who have written him. If they wish him to continue the writing of those Home papers they should spare him all the letter-writing they can.

### THE FUTURE OF CHUNK HONEY.

IN the January issue of *The Bee-keeper's Review* there are two articles on the subject of bulk comb honey, or chunk honey, as it is called in the South. Mr. J. J. Wilder, of Georgia, tells of its merits, both as regards production and selling. Following this article is one by M. P. Cady, of Wisconsin, showing why chunk honey does not meet with favor in the North. As a reflection, after looking over these two opinions, we may say that we believe our Southern beekeepers do not realize that the condition of the honey market in the North is such that the sale of chunk honey is much more difficult than in the South, and that our Northern beekeepers, who possibly have not paid enough attention to this branch of the industry, do not realize that the public will not accept chunk honey in large quantities at the start, but that the sales must be stimulated by careful and painstaking efforts on the

part of the producer or the salesman. There is no question that chunk honey can be more cheaply produced than comb honey, and there are many other advantages attendant upon its production, such as the easier control of swarming, the smaller amount of labor required, etc. However, the experience of such a man as Mr. Cady, who, we think, gave the production of chunk honey a fair trial, should not be overlooked. The following, in Mr. Cady's own words, is a part of the description of his experiment and its result, as given on page 17 of the *Review*.

In order to test thoroughly the desirability of chunk honey, and at the same time to develop a market for the new product, a good salesman was employed to solicit orders direct from the consumers. A fine sample in a flint-glass pail was used in securing orders. The salesman explained the superior money value of the chunk honey, and, being a silver-tongued hustler, he made sales very readily at 12½ cents per lb., at the same time selling, to those who preferred, extracted honey at 10 cents and section honey at 15. However, most of the sales were chunk honey.

While the immediate results were very satisfactory, the final results were disappointing. An occasional patron was pleased with the chunk honey; but more than nine-tenths of the purchasers were emphatic in expressing their preference for *either* extracted or section honey; and, finding it impossible to make sales of the chunk honey, I was obliged to discontinue its production. On the part of the consumers there were three principal objections to chunk honey, as follows:

1. Its mussy condition—being much more so than either straight extracted or comb honey.
2. The flavor of the bulk comb honey was not equal to that of section honey—presumably due to the coating of extracted honey, as in many cases the comb honey in the chunk-honey packages was cut directly from sections that were nearly filled.
3. Candying of the extracted honey in the chunk-honey packages spoiled the comb honey for table use.

An effort to liquefy the candied honey melted the combs, and the resulting mixture of honey and beeswax was a rather disgusting mess to the purchaser who had listened to the salesman's honeyed words in praise of his "pails of fancy comb honey chinked with the finest comb-free honey;" for when the smiling salesman again took the field the sentiment in regard to *chunk* honey was this:

"Throw physic (chunk honey) to the dogs. I'll none of it."

It may be said by the chunk-honey advocates that the foregoing objections are not good; but they were good enough to cause my customers to call for either comb or extracted honey in almost every instance, much to my regret and financial loss, as I had procured a special outfit for comb-honey production.

### SHAKING OR BRUSHING TO CURE FOUL BROOD.

A CORRESPONDENT thinks we are inconsistent when we advise shaking to cure foul brood, and in another place recommend shaking and brushing, or brushing only. In the former case we have used the term "shaking" as indicating a *general* method of cure that involves both shaking and brush-

ing. For the benefit of some who might be misled we will endeavor hereafter to use the terms shaking and brushing, because it is doubtless true that some would shake combs containing raw nectar when they ought to brush.

#### THE MOTH-WORM AND ITS WORK; A DISAPPEARING PEST IN AMERICA.

The half-tone reproduction on page 47 of this issue is a splendid illustration of the work of the wax-worm. These nasty creatures not only soil up parts of the hive and the combs with their webs, but leave their dirt scattered all over every thing. What is more, they seem to have the power to gnaw or furrow into wood as a careful scrutiny of the illustration will show. Very fortunately, however, the pest is fast becoming unknown in the United States. The introduction of Italian bees, and even their crosses with the black bees, is responsible for this. If we could only speak as confidently of the elimination of the brood diseases, the American bee-keeper would have but little to fear from any thing but winter losses.

#### BEEES AND NEIGHBORS.

EVERY season after the honey-flow we are called upon to give advice on how to proceed in case of trouble over the alleged trespass upon the property of an adjacent neighbor. In some cases we advise the removal of the bees; in others we recommend keeping them where they are. In the latter case we supply our bee-keeping friend with literature which he places before his complaining neighbor. We did this in the case of a prominent bee-keeper whose name for obvious reasons we withhold, and received back a reply which shows that our dose of literature convinced the complainant that he had "no case," and apparently the matter dropped. Of course, cases of this kind we always refer to the General Manager of the National Bee-keepers' Association.

#### HONEY DOUGHNUTS.

VERY many are fond of doughnuts and coffee; but when they become a little old they are dry and hard. The suggestion has been made to use a small percentage of honey to keep them moist. Who knows about this, and who can give us a good recipe for honey doughnuts? We know that honey will keep nearly all kinds of baked cakes soft almost indefinitely, the keeping quality depending upon the amount of honey used. Honey-jumbles, for example, twelve years old, as we know by actual experience, are as nice and fine eating as when they were first made. Some years ago we went through a baking establishment and were there told that honey is used because it preserves various kinds of cakes, keeping them moist, where a plain sugar would allow them to dry up in a short time, rendering them unsalable.

In this connection we should like to get reports from those who have a new honey

recipe, either for candy or cakes. Do not offer it unless it is first class, and something that you yourself have tried.

#### ZINC QUEEN-EXCLUDERS; RIGHT AND WRONG SIDE UP.

W. E. BURKITT, Honorable Secretary of the Wilts Bee-keepers' Association, of England, offers in the *British Bee Journal* a suggestion as to the manner of putting on perforated zinc queen-excluders that we believe is worthy of consideration. He says:

#### ZINC QUEEN-EXCLUDERS.

Are those who complain of excluder zinc hindering the passage of the bees careful to lay it on *right side up*? Years ago I saw this mentioned in the *British Bee Journal*, and found the necessity for it, as there is a slight burr from punching on one side, and this should always be placed uppermost, as I suppose many bee-keepers know.

If there is any thing in this idea (and apparently there is), manufacturers will probably see to it that the wood-bound zinc excluders have the zinc so placed that the burr edge will be on the *top* side, for it is apparent that it will be more difficult for the bees to pass the metal loaded than when their sacs are empty. For that reason the easier side of ingress should be presented to the fielders.

For a like reason the zinc excluder-guards should have the burr edge on the inside.

It is practically impossible, in the punching of the zinc, to avoid the burr edge entirely. If the rough side be polished off in a separate machine it will leave a feather edge inside the slots that can not be removed, and this would be worse yet. Attempts have been made to remove this burr; but die and punch experts say that it is impossible to eliminate it entirely, and for that reason there has been introduced the wire-bar excluders, so that bees can readily pass *either* way, because there is no *right* or *wrong* side.

#### THE COVER DESIGN; BEE-KEEPERS OF ANCIENT EGYPT.

WERE the ancient Egyptians the first bee-keepers? Many are inclined to think they were. If the apiaries of Old Egypt were stocked with *Apis fasciata* (which seems to be a purely African bee) they may have been. The Egyptians being kindred to the tribes inhabiting their "pathway of migration" from a prehistoric home somewhere in Western Asia may have led to the introduction of this beautiful species of apis among these peoples. Of course this would easily account for the very close resemblance of Holy Land and Cyprian bees to *Apis fasciata*. Be this as it may, the Egyptians early developed the art of bee-keeping, and, as the paintings upon the walls of their tombs and other edifices show, they employed various methods which, considering the time, show great aptness and intelligence. In explanation of the cover design we will say that the scene is a peep into Pharaoh's bee-yard, showing the keeper studying the bees as they fly about the hives. You will also notice that, chief among the objects shown, is an image of Thoth, their god of wisdom and learning.

This placing of the divinity of wisdom so near to the bees is significant of the fact that, thousands of years ago, the bee was considered useful by man for other reasons than the mere fact that it stores honey.

#### A MEETING OF OHIO BEE-KEEPERS AT COLUMBUS.

THERE will be a meeting of the Ohio bee-keepers at the Neil House, Columbus, Feb. 3 and 4, primarily to form a State organization and to consider needed foul-brood legislation. It is well known that the Ohio foul-brood law, based on the county plan, so far from being a "howling success" is an unmitigated failure. It was against our better judgment when this bill was proposed; but we finally acquiesced, thinking it was better to get *something* than nothing. But we are firmly of the opinion now that we would be just as well off without any foul-brood law, because now our legislators may come back at us and say, "You already have a law," and possibly refuse to grant us needed relief or even a hearing. Of course, there will be other subjects discussed aside from foul brood.

We call upon all the bee-keepers of Ohio to meet with us, for it is high time we were getting ready to do something. Both foul and black brood are spreading within our own borders, and it is important that we take a stitch in time. We ought not to go through the experience of Canada, New York, and some other States, in which brood diseases got a good start before remedial legislation could be put into practical application. Unfortunately, foul brood is getting a start in several sections of Ohio, and our bee-keepers should go before our legislature, now in session, two or three hundred strong, and then keep after our members until we get what we are after.

It is a shame that Ohio, which probably has larger invested interests in bees and bee-keeping than any other State in the Union, should be in a position where it has no adequate legal means by which it can stop the spread of bee diseases within its borders.

Mr. Henry Reddert, 2300 Schoedinger Ave., Cincinnati, O., secretary of the Southwestern Ohio and Hamilton County Bee-keepers' Association, is acting as temporary secretary. Any one interested should correspond with him at once. Please send him a postal, if possible, saying whether or not you can be present. This is a case where numbers will count heavily in our favor; and we propose that the Ohio State Bee-keepers' Convention go in a body before the committee that would have our bill in charge. The sooner we can act, the better.

On Jan. 31 and Feb. 1 and 2 E. R. Root will give addresses on bees, accompanied with the stereopticon, before the agricultural students of the Ohio State University, Columbus. Possibly there are some bee-keepers of the State who would like to come a day or two earlier to take these in as well as the convention at the Neil House on the 3d and 4th.

#### OUTDOOR WINTERING; BEES SEMI-HIBERNATORS; SOME THEORIES BASED ON OBSERVATION.

If the present cold weather continues throughout the Northern States, cellar-wintered bees will doubtless fare better than those on their summer stands. Protracted cold spells, when the temperature is only a few degrees above zero, especially if accompanied by high winds, are likely to be severe on outdoor-wintered bees, even if well protected in double-walled hives with ample packing. For such winters a large cellar, where the temperature can be kept reasonably well under control, is undoubtedly better. We are now satisfied that bees outdoors semi-hibernate during extremely cold spells. A large cluster will contract down to a ball no larger than a double fist. The individuals can remain in that condition, and resist a cold spell for a week or ten days, and possibly longer. During this period they take practically no food from the combs. If the cold lasts long enough, the cluster, stiff from cold, may be immovable, and, being out of reach of stores, may die. Many cases of this kind have we run across when pulling the bees apart the following spring. The slight consumption of stores in some instances would show that the bees died in early winter. Around such a cluster will be a row of empty cells about an inch wide. As the bees are closely compacted over empty cells they simply starve. From some experiments we conducted we do not believe cold actually kills bees; but during this period of semi-hibernation, in this chilled condition, they appear to absorb all the food within their honey-sacs or stomachs, and possibly some of the bodily tissue, the same as true hibernating animals.

If the colony is a powerful one, the cluster may be so large that it does not chill clear through. In that case the center of the cluster will move outward to get food while those on the outside of the ball appear to work inward. Such a ball of bees, by reason of the greater number of individuals, maintains in its inside almost blood heat. If it be torn apart on a cold day, the bees inside will fly out and resent the intrusion just as actively as if it were summer and suddenly disturbed.

Then also it appears that some bees have the power of resisting cold better than others. Experience in our own case shows that at least those strains that have been bred for color will not stand as much cold as the dark leather strains that appear to be more nearly the normal type of the race; but if for any reason the type is changed the ability to withstand cold is decreased.

In the foregoing we have attempted to state what appear to be facts based on a series of observations covering a period of nearly 25 years in breaking into clusters of our outdoor-wintered bees. When dealing with a problem of this kind we have to depend largely on circumstantial evidence; but many a man has been found guilty on circumstantial evidence.

# STRAY STRAWS

BY DR. C. C. MILLER

"TOBACCO—A nauseating plant that is consumed by but two creatures—a large green worm and man. The worm doesn't know any better."—*Calvin Moon*.

MR. PRINTER, did you take liberties with that last Straw, p. 4, or did I write such foolishness? Just cut out that last line but five: "but we thought the bees could spread the combs."

J. B. MARSHALL, p. 29, I've no experience with flour-introduction. Some across the water report it very successful. Likely bees as well as queens should be well floured. Yield of honey at the time may have to do with it.

TO THE MAN who got up that index to GLEANINGS: Here's my hat off to you. [The entire index was prepared by our editorial force. H. H. Root is responsible for the whole of it except the index for editorials, which was prepared by E. R. Root.—ED.]

T. W. RAUM says that, in his part of Canada, alsike must be thrashed in the field and not in a barn, and some can not stand it to thrash it even in the field. I suppose it must affect the mucous membrane. Has that any relation to the reported effects on horses?

DR. R. MUNSON questions Prof. Bonnier's experiment as to bees marked with talc foraging repeatedly on the same spot, for he says bees are always cleaned off before leaving the hive. But Europeans mark their queens indelibly, and might not talc in some way be applied so as not to be removable?

DON'T BOTHER with an uncapping-machine, because you can uncup with a knife as fast as an extractor will take the combs, says p. 753. I don't see the logic in that. If a machine will work faster than the knife, is the time saved of no value for some other purpose? One could at least be reading comfortably between whites.

JOHN H. LOVELL, p. 9, don't be too hard on writers who think bees get honey from roses when it's only pollen. How many beekeepers know about it? But here's a question: When bees dig into cultivated rose-buds, barely opened enough to show a little color, what are they after? Hard to believe they are after immature pollen.

A. I. ROOT, while there is a difference of opinion as to whether cereals should ever be eaten raw, your saying "It is all right to assist the teeth in every way you can," p. 31, may be carried further than you intended. Fletcher says chew till food is creamy, and you can't chew much on soups, while Terry protests against sloppy foods that don't need chewing.

THE BEE-BOOK "Der Bien und seine Zucht" has reached its 11th thousand, and its author says, *Deutsche Bienenzucht*, 177, that no other work of the world's bee-literature has ever

reached such a gigantic success. Somehow Pfarrer Gerstung has overlooked Cowan's British Bee-keeper's Guide Book, with its 45,000. Then there's Root's A B C and X Y Z, which is not such a bad success with its 116,000.

UNUSUALLY mild weather up to Dec. 5, the rest of the year fierce, averaging about 4 above. Yet they say the ground is very little frozen. A 15-inch snow-blanket keeps it warm. [It was mild weather here up to the first of December; then it turned cold, and continued so for practically the whole of the month. It began to warm up again on Jan. 1 and 2, but has turned colder to-day (Jan. 3). The ground has been frozen very hard in this vicinity, for the freeze came before the snow. How this may affect clover we don't know.—ED.]

PROF. H. A. SURFACE is good authority; but his figures in *Economic Zoologist* are a little askew for this "locality." He says cellaring may save 10 to 15 pounds of feed per colony; but trouble and expense of preparing for cellar and moving may be more than added cost of wintering on summer stands. My bees are carried in and out without any preparing, and the cost of moving is less than 2 cents per colony. You can't get 10 pounds of feed for 2 cents. But in many cases his figures may be all right. At any rate, if I lived in Pennsylvania I suspect I would winter outside.

THE EDITOR of *Canadian Bee Journal*, page 436, quotes at length GLEANINGS' editorial, p. 588, and gracefully acknowledges Editor Root's arguments in favor of empty cells in the winter brood-nest so convincing that he gives up the battle. Such an unconditional surrender was hardly necessary. I don't know for a dead certainty, but here's what I think: It depends on the space under bottom-bars. With a half-inch space and combs solid full, the bees will freeze to death; with a space of two inches or more they will be all right. In many cases in my cellar bees fill that 2-inch space with the cluster, and I don't believe the bees in that cluster care whether the cells above them are full or empty. [The editor of the *Canadian Bee Journal* and ourselves were talking about the winter-nest when bees were wintered outdoors. Apparently you have in mind cellar wintering. When bees are indoors it is not very important whether they have a winter-nest, such as we have described, or not; but the fact that they will always make and prepare such a nest, if given an opportunity to do so, when wintered outdoors, seems to show that nature regards it as important. Space under the frames for cellar wintering might affect the proposition; but it would only increase the difficulty for outdoor bees unless the frames were very shallow.

In this connection we wish to convey our acknowledgments to Editor Hurlley, of the *Canadian Bee Journal*. His candor and evident desire to consider evidence is such that his readers will always have confidence in his writings.—ED.]

## SIFTINGS.

By J. E. CRANE, MIDDLEBURY, VT.

One who has the time can not do better than follow Mr. Doolittle's method of reading bee-papers, page 659, Nov. 1.

Page 591, Oct. 1, Mr. Foster suggests the use of scales in the packing room, which is a decidedly good thing. I have found a light spring scale for weighing mail a very good thing for this purpose, and very inexpensive.

On page 587, Oct. 1, it is stated that when there is enough honey-dew to impair the flavor the honey must be labeled "honey-dew." Now, 30 per cent honey-dew would certainly impair the flavor, even if the rest were the choicest clover honey; but would it not be misbranding to label such "honey-dew" when 70 per cent of it is genuine honey? [Yes, in a sense; but the ruling requires putting under the lower grade.—ED.]

### CARBOLIC ACID IN SPRAYING MIXTURES.

On p. 587, Oct. 1, mention is made of the use of carbolic acid in spraying mixtures to keep bees from being poisoned. Can any one tell the proportion of carbolic acid used? I should think that, if enough were used to drive the bees away, the blossoms would be injured. Our Vermont law provides that "a person who sprays fruit-trees when in bloom with a solution containing less than three pounds of unslacked lime to fifty gallons of the solution shall be fined not more than \$40.00 nor less \$10.00." Would not the lime in solution be safer for the fruit-grower as well as the bee-keeper? [See p. 778, Dec. 15.—ED.]

### DISTANCES BEES FLY.

Some interesting views on bee-flights are given by prominent bee-keepers on p. 587, Oct. 1. Now, while it is probably true that bees often fly long distances, it would seem to me equally true that the bulk of the honey is gathered from near-by sources. A neighbor was telling me, not long ago, how in a yard of bees located near the east shore of Lake Champlain he secured surplus honey from only one of two hives, although the rest of the colonies were just as strong. The only solution was, that the bees from these two colonies flew across the lake, where there was considerable basswood, while the rest of the bees did not.

### FULL SHEETS OF FOUNDATION IN SECTIONS.

On page 604 Dr. Miller goes for F. Greiner for objecting to light foundation in sections, and the doctor sums up his reasons by saying that it is his belief that "using full sheets of foundation is of such advantage to the producer that it overbalances several times any disadvantage to the consumer, and hence full sheets of foundation may be

used without any violation of the golden rule." Good! Now, if there is anywhere in the United States a dealer who will pay more for honey in comb built wholly by the bees than he will for that which is built of light foundation, let's hear from him. [Our columns are open for reports of this sort.—Ed.]

Mr. Holtermann, page 592, Oct. 1, makes the somewhat startling statement that half of the honey produced in Canada could be sold locally; and, what is more, he is probably correct. At the recent meeting in Albany of the New York bee-keepers this subject was taken up and similar conclusions reached. By the way, that was a pretty interesting convention. Those New York Staters seem to know which side of their bread is buttered, or, rather, how to butter their own bread. And Prohibitionists seemed at the New York convention about as plentiful as bee-keepers. At any rate, Dr. Miller or Pres. York, of the National Bee-keepers' Association, would have felt quite at home; and, besides all this, it was quite a comfort to me when I got home not to have my wife tell me that I smelled of tobacco smoke.

On page 526, Sept. 1, Wesley Foster says, "When a market is developed for cases without glass that will pay as well as for those with glass we shall be effecting a big saving for the producer." Well, how are you going to develop a market until you put up your honey without glass? There are some rather enterprising bee-keepers in Ontario; and, if you will believe it, they have been putting up honey this year in cases without glass and sending to the city dealer right in competition with glass-front cases, and here is what one dealer says of them: "We like them very much, and thus far what honey we have received in them has arrived in excellent condition. They are a great improvement on the wooden glass-front box, and we think that, in due time, they will be used entirely for shipping purposes."

It doesn't look as though it would be difficult to develop a market there for honey in cases without glass. Of course, the case with which this commission man was so well pleased was our improved paper case that we have had the privilege of introducing the past season.

I was in Boston some ten days ago and called on one of the largest dealers in honey in that city. He did not recognize me; and as he had both paper cases of honey and wooden cases with glass fronts containing some beautiful white honey, I asked him how he liked the paper cases. He said he liked them well. I objected to them on the ground that they did not show off honey like the wood-and-glass cases. He replied that it was true; but he said that the honey arrived in so much better condition that it more than made up for lack of attractiveness. He said further that they had found broken combs in about every tenth case of wood.

## CONVERSATIONS WITH DOOLITTLE

AT BORODINO, NEW YORK.

### FOUL BROOD; HOW DISTINGUISHED—HOW CURED.

While I had foul brood in my apiary during the early seventies, and in two years succeeded in curing the whole so completely that I have had none of that dread disease since (now known as American foul brood), I know that I am not fully up to the times on the foul-brood question. However, as I effectually cured it, and know that the means I used will always cure it, it may not be amiss to give this old plan again. But before telling how to cure it I will tell how to distinguish this disease.

American foul brood is discovered by the apiarist finding one or many cells in a colony containing brood with sunken cappings, and probably a small hole near the center about the size of a knitting-needle, although this small hole is not always present. Upon opening the cells the larva is found stretched out at full length, dead, and of a dark-brown color, dying from one to three days after being capped over. If the larva has recently died it is in shape as perfect as the live larvæ are; but those alive are white, while those dead are of a light-brown color at first, soon changing to a dark brown, and finally to nearly black. Upon touching a dead larva it is found to be a salvy mass, and the whole hive, if far advanced, emits a very disagreeable smell. Some claim this smell is like that of an old glue-pot; but I know of no smell to which it can be compared. The disease progresses, as a rule, very rapidly, and from a few cells in the spring it so spreads that by fall from one-half to three-fourths of the cells will be filled with dead larvæ, the smell of which is nearly if not quite as penetrating as carrion, but not at all like it. Thus what should have constituted an increase died; and as very few larvæ are removed from the cells, the bees grow less and less in numbers until all are gone unless the apiarist comes to the rescue.

I have been thus particular in describing the disease so none need mistake it, and also because there is another disease similar, often called European foul brood, which is not our old foul brood, but what is termed, in New York, black brood. With this last, possibly more larvæ die before the cells are capped over than do afterward, though the caps to the cells where the larvæ die after being capped over have very much the same appearance as the genuine foul brood; but the dead larva is of a yellowish white at first, then a grayish white, and finally brown, while, instead of being stretched out at full length in the cell, it is generally drawn up in a more compact shape, especially soon after it dies. After a while this so dries up that the bees remove much of it; and, if not too bad, when the honey-flow comes on it may

be all removed, the cells cleaned, and the combs filled with honey and capped over, so that, as far as the honey is concerned, no one would know that there had been any disease at all.

Cutting out diseased cells having the genuine American foul brood is of no avail, as the germs of the disease are in the honey. Also, the dead larva never dries up as does that of "black brood," so that all in the hive are removed, although some strong vigorous colonies of *Italians* come very near doing so (if the disease has not progressed too far) on the approach of cold weather in the fall, so that there are only a few cells at that time of the year. However, genuine foul brood is always progressive; and while it may appear to be on the wane in such strong colonies late in the season, yet with spring it comes on again with increased vigor, and always victorious, unless the apiarist is on hand to cure it. This brings us to the curing part.

When a colony is believed to have the genuine foul brood, mark the hive; and if *there are bees enough to ward off robbers* let it entirely alone for three weeks to a month, when it should be examined again just at night if there is any danger from robbers and (if in the breeding season) the genuine will have progressed so you will be sure it is foul brood, while the black brood may simply have held its own, or decreased so as to be nearly all gone. The genuine means *progress* every time, although in some rare cases a colony may hold out over two seasons. As soon as it is determined that the disease is American foul brood, shake or drive the bees into a clean empty hive, render the combs into wax, and *boil* the honey at once before you forget it. Don't set it away thinking you will do it at some other time; for if you do you may repent at a great loss some future day, when, through some mistake, it gets inside, not of one hive, but many of the hives in the apiary. Boiling such honey half an hour or so destroys the germs of foul brood and makes it as good as ever for the bees. If there is plenty of nectar, so there is no danger from robbing, drive or shake off three-fourths of the bees and leave the remainder to care for the brood. In twenty-one days treat again as at first, and a cure will be effected as far as that colony is concerned. After the bees have been in the clean hive long enough for the larvæ to hatch from the eggs laid by the queen in the new comb the bees have built, they can be given foundation, empty combs, or frames of brood, the same as any healthy colony. Burn the hive and frames, or throw them into a large kettle of boiling water, after the foul-broody combs have been removed, and thoroughly boil any thing that may chance to have any of the foul honey upon it. Right here I wish to emphasize the fact that *American foul brood* is in the honey; and if you do this work at a time or in a place so that a robber gets a load of this honey, or carry it on your fingers, knife, or any thing else, to a healthy colony, that colony is doomed.

I have now told you how to cure one hive, so of course you know how to cure a hundred; and if I had a hundred colonies—yes, or twenty—I would go to work in just the way given, knowing that I would succeed; but if I were satisfied that I had only from two to ten colonies in an apiary where from fifty to one hundred were standing I would accept the resolution adopted by a bee convention some years ago, which was this: “Resolved, That this convention believes that foul brood is a very dangerous disease, and that we advise all to be careful in experimenting in regard to its cure. If but two or three colonies are affected in any apiary, destroy hives, combs, honey, and all by burning.” I would do this for the reason that I should consider the risk of experimenting, or trying to cure the two or three or ten greater than the value of the colonies.

[On the above, Charles Stewart, one of the foul-brood inspectors of New York State, comments as follows.—Ed.]

In both American and European foul brood the intensity varies greatly as to odor. I have seen yards where one could smell the disease before reaching the yard; and then, again, where the disease had lost some of its virulence an odor was detected only by placing the comb close to the nose.

Most of the larvae die just previous to the proper time for capping, in a colony affected with European foul brood.

Diseased colonies should be treated as soon as possible when found; as a delay of a month, especially if the bees are blacks, might cause the loss of the whole apiary. It may be necessary to wait until some honey is coming in, as it would be wrong to treat them when robbers are about.

I have seen so much trouble come from feeding back honey taken from diseased colonies, even though it was boiled, that I have always advised against it except in the hands of an expert.

After disinfecting thousands of hives in years gone by, we find we get the same results without this work. The brood-frames are boiled as much to clean them as to disinfect. Bees can be treated right in their own hives, taking away every cell of comb and replacing with frames of comb foundation. Formerly it was thought necessary to shake again in three or four days; but we find the average number reinfected is about one in ten, so we prefer to watch these colonies treated, and treat the tenth one rather than treat all of them a second time. If I found but one or two colonies in a large apiary affected but slightly I might destroy them at night when all bees were in the hive; but if badly affected I would treat them, feeling certain that other colonies near them would soon show the disease and would have to be treated. That is, if a colony had the disease long enough to show it badly, others near it would be almost certain to contract the disease.

## BEE-KEEPING IN THE SOUTHWEST

BY LOUIS SCHOLL, NEW BRAUNFELS, TEX.

### PROSPECTS IN TEXAS FOR 1910.

Prospects are good. It has rained bountifully in most parts of the State at least, and we are expecting the return of one of those good old-fashioned Texas honey-yields next season. Owing to the lateness of our fall, and almost a total absence of cold weather until in December, several sources such as cotton, broomweed, and some minor plants, yielded some nectar and pollen right along until the cold weather cut it off. This gave the bees a chance to fill up their brood-nests and rear a lot of extra brood. These young bees will be most valuable next spring, and hence the colonies are in the best possible condition for winter. With an early opening of spring next year the bees should be in fine shape for any honey-flows, no matter how early they come. However, the spring may be late, as it has been unusually warm so far this winter.

### ALFALFA HONEY IN TEXAS.

As yet there is very little of it produced since the area planted in alfalfa is not yet very extensive; and in many places where it is planted the atmospheric or other conditions that seem to exist cause it to yield no nectar. The most luxuriant growth of alfalfa, in large fields within a mile of an apiary, have been found destitute of bees, while in other parts of the State the alfalfa was visited well and resulted in some surplus honey. These differences have occurred with alfalfa with and without irrigation, and upon several occasions in the same fields—that is, at certain times bees worked on it and at others left it entirely alone. This is an important subject for scientific investigation, especially since a great number of people are inquiring more and more as to whether alfalfa is good for bees in Texas. It's up to our experiment stations.

### BULK COMB VS. SECTION HONEY.

That description of Wesley Foster's workshop, p. 725, gives one the “shudders” if he is not used to such things himself. Culls still unsold in November; No. 1, 2, and 3 grade and close grading; scraping separators and section-holders; twenty to thirty thousand sections to fold and starter; broken tins, cracked section-holders and separators to repair; besides the selecting and discarding of daubed and stained sections that have been on the hives but not finished, etc. All this makes us Southerners wonder whether section-honey bee-keeping is worth while. To this must be added the extra care of the bees in the early spring toward getting them strong enough so they *can* work in the section-supers; later, coaxing them into these supers so they *will* work in them; and even after that they must be coaxed to finish the

sections properly and to fill each individual section just so. First the colonies must be *stimulated* and the hive *expanded* to obtain rousing colonies for best results; this obtained, the hives must be *contracted* to force the bees *up*; but it generally forces them *out*, as swarms; and this must be checked after the bee-keeper has brought them up to this point. Finally, it all depends on how well one succeeds with the above whether he makes a crop of section honey or not. If he makes a crop, then we come back to the grading-rules, etc., alluded to above, so that, taking it all in all, we wonder why others are still following along an old rut—that of section-honey production, which is the most expensive way of producing honey. In Texas we abandoned this method long ago for something better and more profitable—the production of bulk comb honey. It is easier to produce, it yields larger crops, sells better, and results in the most dollars.

#### AN AUTOMOBILE FOR OUR WORK.

A thousand colonies of bees in twenty or more apiaries, scattered from a few to nearly two hundred miles from home, and only one assistant as help, has brought up the question of getting around from one place to another as fast as needed; and how to solve this question is the subject now before us for the coming year. While we have managed to do nearly that much heretofore by the use of several teams of horses, it will be quite out of the question thereafter if our plans for still more extended operations develop.

The automobile may be the only thing to solve the problem; yet we realize that it is expensive, if a good one is to be used, and the cheaper ones, so far, are not as reliable, especially during the height of the season. We have studied the many different makes, and although we have not yet found just what we want, the coming season will find us flying (?) from yard to yard in a "machine." We figure this way: If we depend on horses we must purchase two more in addition to the one horse and two mules we are now using. Figuring the cost of these, extra cost of a new lot and stable (for we live in the city), their feed and extra care, morning, noon, and night, we encounter quite an expense in a year. Besides, they eat whether at work or not, and need the same daily attention. Would they not in the long run cost more than a machine? This is not all. If we take a trip to one of our yards 20 miles away it takes about 4 hours to go and 4 to return, leaving us 2 hours for work out of a ten-hour day; and on a hot summer day not only the horses but the persons are tired out from the long weary drive. With an auto just the reverse is true, a two-hours' drive and eight hours of work, also the enjoyment of the recreation obtained on the way. These are not theories, for we have had some experience in this matter. We are sure that, with the use of a good reliable machine, more than twice as many colonies

of bees can be managed by one man, and that, as soon as we have better perfected automobiles or motor-vehicles, and the prices are lower, more bee-keeping will be done *a la* automobile. The question now is, "What kind of machine should the bee-keeper adopt under present conditions? Who can advise us?"

#### THE TEXAS PEOPLE AND ALFALFA HONEY.

Owing to the fact that very little alfalfa honey has been produced in Texas, the people, as a matter of course, have not become used to its flavor. Hence its sale in many markets, into which it has been shipped from Colorado and other points of the west, has been comparatively slow, and in many cases some trouble has been experienced on the part of some of the purchasers as a result of its unfamiliar flavor. Many are the complaints made regarding this honey, the main one being that it is adulterated—not real honey; others that it is spiced. Some people can not stand the flavor, hence can not eat it as they do our real Texas honey. The most unique description given of alfalfa honey, and that by numerous persons, is that "it is too white—hasn't any real honey color to it, and is strongly flavored with cinnamon." Many purchasers will not buy alfalfa honey a second time, and would not the first if they had known its flavor.

Our experience at the fairs annually has put us in closer touch with people of this kind, and it is amusing to hear the different complaints, which are only a lesson to us, and show the necessity of more education to the general public on these matters.

That experienced bee-keepers themselves should have trouble in the respect above mentioned would seem ridiculous, but it is a fact. In our exhibits a year ago a certain bee-keeper sent some section honey of as fine white quality as we have seen. At the close of the fair this honey was left at the secretary's office together with three other and similar packages of section honey. These were changed about in some way, and our bee-keeper, without knowing it, got a case of the others when the honey was returned to him. The sections being the same style in each case he did not recognize any difference until it was put on the table. It was hurried back to the secretary's office, with the declaration that it was not his honey—that this was "adulterated, and flavored with cinnamon," and he desired *his* honey back. The matter was referred to me, and I was asked what had been done with this man's honey. Investigation later showed that his honey had been taken by another party, and alfalfa substituted by mistake.

---

#### POLLEN ABOVE EXCLUDERS.

On page 690, Nov. 15, Dr. Miller remarks that he puts combs with pollen over an excluder, and it is not long before they are cleaned out. Over the excluder is the place where I am bothered the most. I have to clean out a big lot every spring, from supers. Bees fill a lot of frames with pollen where I want honey stored.

Rancocas, N. J., Dec. 18.

S. B. HUSSEY.

# GENERAL CORRESPONDENCE

## THE CONTROL OF BEE TERRITORY.

At the Present Time No Bee-keeper has a  
Legal Right to his Territory; Is a  
Moral Right Sufficient?

BY DR. C. C. MILLER.

Some time ago Mr. J. L. Byer threw out a sort of challenge for me to define my position with regard to the matter of occupying bee-territory, with a slight intimation that there was something not just right about my position. Mr. Byer is a man whom I hold in high esteem, and I should like to justify myself in his sight; but I have delayed and hesitated to reply, partly for want of time, partly because Mr. Byer was just a bit vague, and I didn't know just where to take hold, and chiefly because I did not feel sure the time was ripe for any discussion of the matter.

Years ago I made the attempt to advocate the idea of having such legislation as to allow each bee-keeper to have control of a certain territory, so far as bee-keeping is concerned. I do not know whether any one agreed with me in thought, but certainly, so far as I remember, no one agreed with me in word, for no one publicly agreed with me, and I stood entirely alone. All who expressed themselves at all on the subject opposed me, notably my good friend Prof. A. J. Cook.

If I thought there was no change in sentiment I would not consider it worth while to occupy space for a single line on the subject. But I know there has been change, at least change as to *expressing* opinion. In Colorado, if I am not mistaken, a rather emphatic resolution was passed to the effect that a man who would encroach on territory already fully occupied by another was not quite what a good man should be. In the Imperial Valley the bee-keepers have banded together in making common cause against such intruder in such a way as to roast him out. In far-off Australia they have gone perhaps to the extreme of the desired limit; and a man by paying a small sum may plant an apiary with the assurance that no one else may locate a hive within a certain limit.

I think there is a general belief that a man occupying territory has a certain priority right in that territory—a moral right; but with regard to a legal right there is entire apathy. As nearly as I understand it, the belief is that there is no need of any legal right, or that if there is any such need it is not possible to obtain it. I will not discuss just now the latter point. But I want to repeat with all the emphasis I can command what I have said so many times, that if ever bee-keeping is to stand upon a firm basis like other lines of business, there must be such a condition of affairs that the bee-keeper shall feel just as secure against interfer-

ence as the stock-raiser who is assured by the law that his fields shall be occupied by his cattle and by his alone.

That, friend Byer, is the foundation-stone, the keystone of the arch, and all the other figures of speech you can imagine as to any views I may hold. If you will show me I'm wrong in that, I need take no time to tackle any other point. And because I hope it may do just a little good in bringing about the day that I think will some time come, although probably not in my time, I ask a place on the stage for a while, Mr. Editor, to speak my little piece.

There are some—good men too, like W. M. Whitney, who think any man has a right to plant an apiary wherever he can get enough square rods of ground for its occupation, without any regard to surrounding bee-keepers. Granting that they are right, that makes it all the more important that there should be some way whereby, without doing injustice to others, I may be able to obtain control of a certain territory, for they take away all moral right, the only right that any one can now claim to a given territory.

Others, perhaps, believe heartily in priority rights, but think there is a strong enough moral feeling in the minds of all bee-keepers to make these rights respected, so that no legal right is necessary. Such people need to be told that these rights have not always been respected in the past, and there is no reason to believe that they always will be in the future. If they have always been respected, why should vigorous resolutions have been passed against offenders? why should Imperial Valley bee-keepers unite to punish offenders?

On page 673 Morley Pettit says that infringing on territory so as to overstock it is a boomerang. It is. Suppose a man plants an apiary in a locality I already occupy fully, he will suffer from the boomerang in the way of failure of crops; but how about *my* crops? Don't I suffer as much as he? And is it the square thing thus to oblige me to pay for his tuition?

Very pertinently Editor Root asks, p. 674, "How are we going to educate him so that he will be 'wise' enough not to locate there in the first place?" Even if you could do so, there's room for a whole lot of trouble. If Smith has a single colony, it would hardly be the fair thing for him to warn off all who should want to locate within a mile or two of him. Suppose he has 10 colonies, it would be much the same. Suppose he has 75, and he thinks that any increase of numbers would result in loss instead of gain. I think differently. I think 100 colonies would find support on the same ground. I plant an additional 25 colonies close beside him, so as to save the nectar from going to loss. If he is right in his view, then he is suffering a real loss from my intrusion. But who can decide? I've been more than 40 years trying to learn how many colonies my locality will bear, and I don't know yet. If he had a *legal* right to the territory, then there could be no trouble.

Suppose another case, and not an uncommon one. Suppose Jones has found a favorable locality where a hundred or more colonies can easily be supported in one apiary. At considerable expense he moves to that locality, starts in with 25 or 50 colonies, and expects to build up to 100 colonies. Claiming that the field is not occupied, I plant 50 colonies right beside him. Pretty rough on Jones, but I insist the field was not overstocked, and who is going to tell me I've no right there? There's no such conflict about a cow-pasture; and why should there be as to a bee-pasture?

There are other ways in which trouble may come—in which trouble has come. I tell you, good friends, the present loose way has never been satisfactory, and never will be. I suppose I've had less interference than the majority, but I'd give a fair price to-day to have absolute control of a given territory. I suspect there isn't a possessor of 50 colonies anywhere in the land who does not feel the same way, although it may not be popular to say so. Is there any good reason why a man who makes his living from bees, or part of his living, should not feel just as secure in his field as the man who makes his living from cows? Just keep this in mind: *No bee-keeper in this land has a legal right to his bee territory.*

Marengo, Ill.

## EUROPEAN FOUL BROOD.

### The Cure *à la* Alexander.

BY C. F. BENDER.

Dr. Miller's excellent articles on European foul (or black) brood remind me that perhaps I owe the bee-keepers an article on this important subject. I am glad to see that the doctor has tried the Alexander method. Shaking on foundation has been recommended so persistently that many of us hardly realize that there is another and a better remedy.

My experience of the past seven years has convinced me that there are only two methods of treatment worth mentioning for either form of foul brood—the shaking plan, with or without starvation, and the method of dequeening for three weeks and requeening with hardy stock. For the American form the dequeening method is useless; for the European form it is safer and better than the foundation treatment.

I had practiced the Alexander plan, without knowing it, for two or three seasons before it was put before the public. The way of it was this: In the summer of 1905 I had begun to run short of bees from repeated losses. As most of the affected colonies were strong I shook them on foundation and set the brood in a new location to hatch out, intending to shake the combs again at the end of three weeks, and form new colonies with the young bees, thus treating them and getting increase at the same time. When the brood had all hatched out those combs and

bees looked so clean and smelled so sweet that I decided to requeen them, and try them another season. They stayed healthy; but as I had requeened at the same time with different stock, I hardly knew whether to attribute the cure to the stock or to the dequeening. To be on the safe side I kept on doing both, and still think that both are necessary.

Since the Alexander articles came out I have been following his plan as a regular routine. About the first of May I begin examining all weak or otherwise suspicious colonies. When one is found with dead brood the queen is promptly killed, even if that means the probable loss of the colony. Toward the last of May the queens, instead of being killed, are used to requeen the earlier cases, though only temporarily, as they are usually killed later, and young queens of other stock substituted. The doctor tells us not to attempt treating weak colonies, and he is entirely right; but he does not go quite far enough. Instead of uniting before treatment we must unite before they become diseased; that is, we must never allow a weak colony on the premises.

"To bee or not to bee," that is the question to the novice who has a serious outbreak of disease. It has been such an important question to me that I think I have been rather careful in making experiments; I know I have been careful in keeping records; and these same records have taught me to drop entirely the nucleus method of making increase. Sixty per cent of colonies built up from nuclei, though apparently healthy the first year, will develop the disease the following season. So I think best to make all increase from natural or shaken swarms.

After this disease has once started in an apiary there are three principal ways in which it spreads: By exchange of combs, by robbers, and by nurse bees entering the wrong hive after taking a flight. Of course, all exchange of combs should be stopped at once. Strong colonies and Italian stock will control the robbing if one is at all careful about opening hives during a dearth of honey.

I am a little diffident about speaking of the spread by nurse bees, because I have never heard any one mention it as a matter of any importance. But the fact seems so clear to me that I will tell you how I came to notice it. My hives are arranged in pairs, mostly facing south, with six to ten feet between the pairs. In April, 1906, the first case of disease occurred in a left-hand hive toward the front of the apiary. About two weeks after I had discovered this case, two more appeared in hives immediately behind the first, both on the left-hand side of the stand. The cases kept coming in regular sequence until there were ten, all except one on the left side of the stand, forming nearly a regular row across the apiary. I could see no explanation except that it had been carried by bees entering the wrong hive, most likely by nurse bees which had been caring for the brood in the infected hive, and im-

mediately began the same work on entering the healthy one. Since then I have seen the same thing often, though not so strikingly. The remedy, of course, is to spread the hives as much as possible, and to face them in different directions. But I think it is perfectly safe to keep them in pairs, as I never knew bees to mistake right and left.

An odd thing is that robbing infected combs does not always cause the disease in the robbing colony. Three years ago colonies number 34 and 59 went partners in robbing out a stack of diseased combs. Neither one has ever shown any dead brood. I have reared queens from both, hoping to get stock that was more or less immune, but am not sure that I have it.

Two things the novice is always anxious to know when he finds dead brood; first, what disease is it? second, whether it is going to put him out of business entirely. Regarding the first, I think the roping test is a sure one. Twist a toothpick in the oldest dead larva you can find; pull it out; and if it draws a thread, call it American foul brood. If it does not draw a thread, and smells sour, call it European and kill the queen.

Regarding the second question, whether it will put him out of business entirely, no; not unless he wants to quit. He can save eight colonies out of ten by proper treatment. In the case of European foul brood I think about three out of the ten would get entirely well in the course of time without treatment of any kind. But in the mean time they would be worse than useless, and would spread the disease to every other colony within flying distance.

Newman, Ill.

### PAINTING HIVES.

What Paint to Select, and how to Mix;  
Complete Instructions from a Prac-  
tical Painter.

BY C. G. HULICK.

The part that usually gets the amateur painter into difficulty is the buying and mixing of paint. My experience as a house painter, from 1896 to the present, shows to me that there is no better and cheaper paint than pure white lead and pure raw linseed oil. The purity of these two parts is essential to a durable paint. Most people do not know that pure oil is the basis of good paint. Linseed oil is the only good oil known to the trade. Pure raw oil *boiled* in a kettle has a much "heavier body" than the so-called boiled oil, of which a circular issued by a prominent Chicago paint-manufacturing firm tells us is heated only to near the boiling-point, a dryer added, and sometimes other adulterants. White lead and oil are not hard to get mixed if only a small quantity of oil is added at a time.

To mix the ingredients, lift some lead into a bucket and stir, if possible, before adding oil; then pour in half as much oil as there is lead, and stir until thoroughly mixed. Add

half the quantity of oil as before, and stir. Repeat until thin enough to spread well but not run. Then put in from a half to one pint to the gallon for winter painting, and one-fourth to one-half pint for summer, of Japan dryer when raw oil is used.

This is where I differ with F. Dundas Todd, who does not use dryer. In this climate, paint mixed with raw oil would wrinkle if used in cool or cold weather, and that is where many of us have time to put together and paint the hives we use. Japan dryer causes the paint to dry from the wood out instead of skimming over and wrinkling with the cold. Raw oil dries very slowly in cold weather, page 657, 1909.

For hard pine knots and pitchy lumber, use turpentine in the first coat—one pint to the gallon.

Painting hives adds durability and neatness; keeps ants away; keeps water out, etc. This spring I bought some dovetailed hives, two years from the factory, that had only one coat of paint. When I began to paint them I found the bottom-boards almost gone, rotten inside, as well as badly cracked all over, proving to me that hives should be well painted.

Why do Dr. Miller and Mr. Doolittle not paint their hives? Why should we let hives waste by decay when paint will preserve a hive as long as a house? The advancing price and decreasing quality of lumber makes the strongest argument for preserving the hives we have. I paint the dovetails, rabbits, and joints of all bodies, covers, bottoms, and supers, and give them three coats of white lead and oil after nailing. We have enough moisture here to use up an ordinary hive in about two years, unpainted. Do not the bees deserve the most comfortable moisture-proof house to live in that we can give them? Buying bees in old, rotten, and shaky hives makes one look with much pleasure on sound well-painted hives.

Ainsworth, Iowa.

[We are glad to indorse all of these suggestions. There is nothing better than a pure white lead and linseed oil. In this connection we wish to caution our readers against using cheap ready-mixed paints. The pure-food and drug act does not prevent wholesale adulterations of any article of manufacture not calculated to go into the human stomach. The consequence is, there are but very few brands of ready-mixed paint that are pure; and even some that are contain too large a percentage of zinc. While zinc is good for inside finished work, it has a tendency, when mixed with white lead for outside work, to scale, and hence after a time the house looks flaky. Even after it is repainted it looks badly, and, what is worse, some of the old scales will flake off, carrying with them the new paint. A pure white-lead paint, after it has been on wood a good many years, will chalk like powder. A second coat of pure lead and oil right over this will combine with the lead pigment from which the oil has dried out, and make a good, new smooth finish.]

If one can not be sure of getting a ready-mixed paint that is pure he had better buy pure white lead and oil and mix them as directed in this article. But perhaps the reader would like to know what lead paste is pure. There are several good brands, among which we might mention Morley, The National Lead Co., and Sherwin & Williams.—[Ed.]

## AN APPEAL TO NEW JERSEY BEE-KEEPERS.

BY ALBERT G. HANN.

On Dec. 18, at the last annual meeting of the New Jersey Bee-keepers' Association our foul-brood bill was thoroughly discussed, section by section, and approved; and the members present determined to do all they can to get the bill enacted into law at the present session of the legislature. But there remains much to be done by all other bee-keepers in the State. In the first place we should like all other members who have not done so to send us their annual dues of 50 cts. for 1910, and ask for a printed copy of our bill. Then we want all the other readers of GLEANINGS to join our association, send us the annual dues of 50 cts., and get a copy of our bill and enjoy the privileges of membership.

If there are any readers who do not see fit to join us we should like to have them write us, enclosing a stamp, asking for a printed copy of our foul-brood bill, and tell us if there is any disease among their bees, or if there are any careless bee-keepers around them, or if there are any box hives.

We are asking the readers to join our association, for, the larger our numbers, the greater prestige it will give us in asking for a bill. If only a few ask for this bill it will look as if they were trying to create an office for one of them. Then the association needs more funds to carry on the work properly. There is considerable expense connected with getting a new piece of legislation enacted like this, such as postage, printing, telephone fees, and traveling expenses. It is not fair that this should be borne by a few bee-keepers, as the law benefits bee-keepers throughout the whole State.

By the time you read this, our bill will have been introduced. We want to urge every reader of GLEANINGS to write to their senators and assemblymen from their respective counties to support our bill. Write a short business-like letter; explain briefly what foul brood is—that it is a germ disease; how it spreads by infected honey; what a danger the careless bee-keeper is, and how our bill will help eradicate the disease. Compare our interests with the dairyman's interests, and explain that the bee-keeper's property has just as good a claim to protection against contagious diseases as the cattle-raiser has to protection of his herds against contagious diseases by legislation. We have laws protecting cattle against contagious disease. Mention further that California, Colorado,

Idaho, Michigan, Nebraska, New Mexico, New York, Ohio, Texas, Utah, Washington, and Wisconsin have foul-brood laws; that Connecticut and South Dakota passed foul-brood laws last winter, and other States are trying.

We should like to ask especially those interested in bees in Essex Co., Hudson Co., and Union Co., to see and to write to their assemblymen and senators from their respective counties. Those three counties contain a majority of the members of the assembly, and therefore we must get them to favor our bill. *Without the favorable action of the assemblymen from those three counties our bill will fail.*

I trust that this will be our last effort, and that we shall succeed, as, indeed, we will if each bee-keeper will do his part.

*Join our association now.*

## VENTILATION BY RAISING THE HIVE-BODY OFF THE BOTTOM.

**By its Use all Loss can be Prevented in the Winter, and Almost all Swarming done Away with in the Summer.**

BY A. A. CLARKE.

I have been interested in the discussion on the subject of ventilation of hives by J. A. Yeoman, page 638, Oct. 15, and the article by the editor on page 504, Aug. 15th issue. This confirms what I wrote in GLEANINGS, page 970, July 15, 1907, when I sent my method of ventilating in the summer time. I have been using a similar method of ventilation in the cellar, as that is where we are compelled to winter our bees in this latitude. I have adopted this scheme of ventilation as being the most practical and sure way of wintering for our uncertain winters. I am after results, not theory. I have demonstrated that, with sealed covers, plenty of stores, and young queens combined with proper ventilation, there is no fear of weak colonies in the spring. When my bees are put into the cellar every hive is weighed; then the regular entrance is placed next to the wall, and the body of each hive is loosened from the bottom-board, and, with the hive-tool, is pushed backward until the same width of entrance is secured at the back of the hive. My cellar is so constructed that I can keep the temperature within one or two degrees of 45 continuously until the bees are put on summer stands. I have not lost a colony since I have first used this method; and last spring, which all know was a severe one on bees in this locality, my bees were as strong when removed from the cellar as when put in; and they were all strong enough to gather a nice surplus from fruit bloom and dandelion. Perhaps it will be as well for me to say that I have very little time during the season to attend to my bees, and that is the main reason why I had to study out some plan to get the best results in honey from them.

I am so situated that I have to drive five miles all the year round to my place of business, rain or shine; and when it is time for bees to leave the cellar it is my busiest time also. Since I have adopted the ventilation outdoors and in, I have not had ten swarms per year from 100 colonies; yet I run my bees chiefly for comb honey. When very hot weather comes I use the wedge as illustrated in GLEANINGS some two years ago. When it gets to be 100 in the shade, as it does here most summers for a time, each hive is raised at the back with a wedge the same as at the sides. This appears to be all the ventilation needed for the bees to keep on working, no matter how hot it gets. If this ventilation is allowed to remain for the rest of the hot weather, according to my invariable custom, the bees will use it as an entrance, providing they are well supplied with a strong working force of bees. Then if enough room for storage above is given them they will not swarm—at least that is my experience. Always let this ventilation at the back remain until there is danger of robbing, then go along and remove the wedge.

Le Mars, Iowa., Nov. 24.

## THE CHICAGO-NORTHWESTERN CONVENTION.

BY R. F. HOLTERMANN.

The above association held its thirtieth annual meeting at Chicago recently with G. W. York, the president, in the chair. The convention in one respect was like our recent Ontario meeting. It spent a very considerable time over the question of foul brood (American and European), and the convention was unanimous in its desire to secure legislation for the State of Illinois, by means of which it could secure authority for the inspector to examine colonies of bees, even if contrary to the will of the owner; also to authorize the inspector to destroy badly diseased colonies. It appears the State has, up to the present, no such law.

### TREATMENT OF EUROPEAN FOUL BROOD.

Doctor Miller gave the following condensed treatment of European foul brood: Brush from all but one comb of brood the bees. Allow this comb to remain in the hive, putting beside it two empty combs. When eggs are found in one of these combs take out the original comb. Take away the queen; ten days later destroy all queen-cells and give the colony a virgin queen. Dr. Miller recommended making colonies with European foul brood very strong. Mr. Cavanaugh suggested shaking the strongest diseased colonies, giving the brood to weak diseased stocks, strengthening them, yet not increasing the number of infected combs.

### BETTER-KEPT BEES.

Is it better to keep more bees or to keep fewer bees better? This was a question before the convention. A member said, keep more bees and keep them better. It was al-

so stated that badly kept bees are a menace to the good bee-keeper on account of the foul-brood danger.

W. Z. Hutchinson stated that the idea that many had (that the one having many colonies of bees must neglect them) was not so. He had traveled about a good deal, and found that, when a man had many colonies, he was more likely to look after them, his attention is drawn more to them, and he becomes more interested in that line.

### POLLEN IN SECTIONS.

A method was given to remove pollen from sections. Take a toothpick, break down the comb about the pollen, and break into the pollen and return the section to the hive. The bees will remove the pollen.

### SIZE AND KIND OF HIVE.

This question came in for consideration. One who had several hundred Heddon divisible-brood-chamber hives, and had used them for many years, stated that he found the divisible feature a weak point in outside wintering. What next? Here I had almost become a convert to the divisible-brood-chamber hive because I had been told and believed that the above was a strong feature; also that bees in such a hive would build up better in spring when a man of long and wide experience states the first is not correct, and Mr. Townsend, in GLEANINGS, states that the bees in such a hive do not build up as quickly in spring. Such divergent conclusions only go to show that a government apiarist, who is only a man after all, had better leave tests along such lines alone, for in that capacity his experience must be very limited compared with men we know of who come to diametrically opposite conclusions. We do not find other departments testing and giving out orders of merit in reapers, mowers, plows, manure-spreaders, etc. The bee-keepers, in my estimation, can get better value for the money expended in having the governments—federal, dominion, state, or provincial, carry on experiments where equipment and time needed make them beyond the bee-keepers' reach. The number in favor of the large hive showed an increase.

A question was propounded as to what constitutes an eight or ten frame hive; and to settle this question for all time a vote was to be taken. Some claimed that, if the super was used as a brood-chamber, then the number of frames in the lower story no longer constituted the size of the hive. The convention voted contrary to this idea.

### HOW MUCH WAX IN TEN LANGSTROTH COMBS?

In reply to this question it was stated that N. E. France had secured 3 lbs. of wax from ten Langstroth combs. Holtermann stated he had no doubt this was correct, for he had experimented in this direction, weighing the wood frames, then putting 2½ oz. of foundation (a full sheet) in each frame. Upon weighing the combs after completion he had found that the bees had added 2½ oz. of wax to the foundation in each comb, thus completing it. This would make a total of 3 lbs. 2 oz. of wax to a set of ten combs.

## COLOR OF BEESWAX.

Quite a discussion took place on the above subject. One member was prepared to swear that the bees secrete yellow wax when working on the goldenrod; but when the convention wanted to know upon what evidence he was prepared to swear, he did not give a very satisfactory answer. The point was, did the yellow color come from the pollen after the scales were secreted? Some one stated that the wax would be according to the color of the honey. This was easily disproved, from the fact that buckwheat honey gives white wax. Dr. Miller stated that, contrary to some high authorities, he found that wax is sometimes, at least, quite white. He had taken virgin comb and melted it into a small cake when it was still white.

Brantford, Canada.

## A BIBLIOGRAPHY ON BEE-KEEPING.

BY DR. E. F. PHILLIPS,

*of the Bureau of Entomology, Washington, D. C.*

It may be stated with little fear of contradiction that we all write too much, not only concerning bee culture but on all other subjects. It is impossible, however, to stop the increasing current of bee books and pamphlets, and articles in bee journals, and it becomes necessary to devise some way to keep track of what is written, not only to aid in keeping up to date on the subject, but to prevent the repetition of work already done and to check up various claimed discoveries. The need of a bibliography on bee-keeping has been very strongly felt in connection with the work of the Bureau of Entomology on apiculture, and to satisfy this need at least partially such a bibliography has been begun. I shall here attempt a brief description of it for the benefit of those who may desire to start something similar.

All records are made on cards (linen ledger paper) 12.5 by 20 centimeters in dimensions (approximately 5 by 8 inches). This size was chosen rather than the 3-by-5-inch cards usually used in libraries because of the need of space for abstracts and notes, and also because cards of this size are used for the records and notes of the office, and the subject bibliography cards can thus be arranged right with our own notes. All reference cards are made at least in duplicate. One set of the cards (blue) is arranged in alphabetical order under the names of the authors, and another set (yellow) is arranged according to the subjects treated. In case an article treats of two or more subjects, as is often the case, separate yellow cards are made for each subject. In the case of books devoted exclusively to bees, the subject catalog is not attempted, for it would be an endless task. In all such cases the yellow cards are filed in the drawer containing the book catalog. For example, Dr. Miller's "Forty Years Among the Bees" is cataloged thus:

Miller, Charles C., M. D.,  
1903. *Forty Years Among the Bees*. Chicago: George  
W. York & Company; 327 pp., 111 text figures; 13x20 cm

The blue card containing this record is filed under Dr. Miller's name, and the carbon copy on the yellow card is filed in the book catalog under 1903. Both cards are stamped "Book," so that in case either is removed from the files it can easily be replaced properly. The size of the book is given in centimeters rather than to mark it octavo, since such designations vary greatly in their use.

In the case of articles in journals the name of the journal takes the place of the publisher in the case cited. Anonymous publications are filed in chronological order in a separate place. All articles by one author are arranged under his name in chronological order in the authors' catalog.

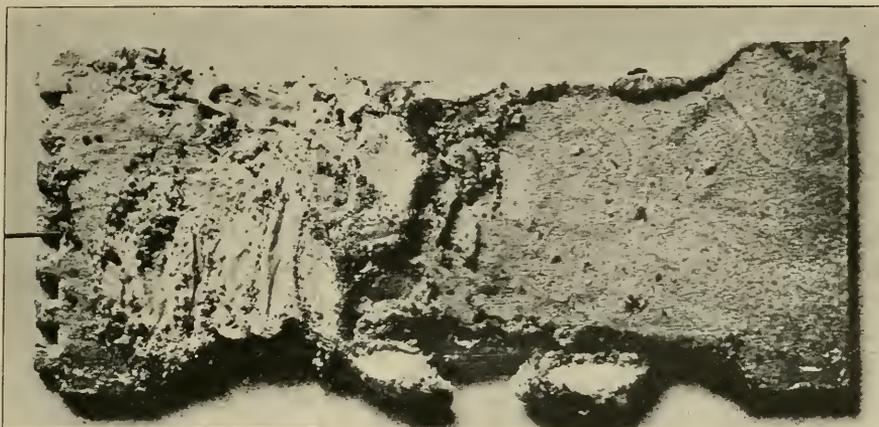

In some cases references are obtained which do not indicate under what subject the yellow card should be filed, in which event the two cards are fastened together and filed under the authors' catalog until the article can be looked up.

In case an article is of enough value to warrant an abstract or translation (in the case of articles in foreign languages) these are either written on the yellow (subject) cards or on thin paper cut to fit envelopes which are just the size of the cards. On these envelopes is written the bibliographical reference, and they are filed under the proper subject. For example, in our bibliography on disease we have translations of all the important foreign papers on this subject, and numerous abstracts and notes on the subject cards where the articles are of less importance. In this way the subject catalog becomes an important storehouse of information.

This bibliography was begun about two years ago, and now contains between 16,000 and 18,000 titles. The Drory bibliography has been copied complete; the DeKellar bibliography, which is very inaccurate, has also been included; but the titles and references are corrected in many cases. The Taschenberg catalog of articles in journals has also been included as well as numerous smaller lists. In each case the source of the reference is stamped on the card, so that any errors can be traced to the proper source. Where the references are made directly from the books or articles, the cards are stamped "Verified." The available bee journals are now being cataloged. This is an enormous task, but is proving of great value. Numerous articles not directly on bees, but which are used in our work, are also included in the bibliography.

All of this indexing means lots of work for the winter months, but we are fully repaid by the ease in finding literature that we need. Unfortunately these cards are not available to other workers in bee culture, but will be freely accessible to any one desiring to consult them in Washington. Naturally they can not be sent away from the office.

To publish such a bibliography would be very expensive. It is constantly growing, so that it should be printed on cards so that new titles could be inserted in the proper

A sample of how the eggs and cocoons of the bee-moth are deposited on wood. Sometimes the wood is grooved or eaten out. The illustration fails to convey the real filthiness of the mass.

place. Perhaps this never can be done; but at any rate we shall aim to make it a bibliography which will serve our purpose in the work of the Bureau, and it may be of use to those outside who are in a position to consult it from time to time.

Bureau of Entomology, Washington, D. C.

### MOTHS DESTROY ENTIRE COLONIES.

BY C. E. MILLARD.

I have 40 colonies of the common American brown bees. Since July 1 the worms have destroyed seven hives, and by next swarming time they will no doubt destroy the entire lot unless I can find a remedy.

If you think that another breed of bees will be any advantage I will change stock. To be sure, I do not see how this would help; but I refer the matter to you. What I have are doing well except for the worms. But they are something fearful. I send you a sample of the worms and also a piece of a section, that you may see the form of the pest and the nature of their ravages. It hardly seems possible that, in so short a time, there could have been so many worms, and that they could actually cut away the *solid wood* as they have done. Parties who have seen the condition of things are amazed.

Ravenel, S. C.

[The whole trouble is due to lack of care, especially among queenless colonies. Since the Italian bees have replaced the old-fashioned black bees, most of the trouble with moth-worms has disappeared. Your easiest remedy will be to destroy your old black queens and get full-blood Italians. As soon as they hatch out they will go to work cleaning out the worms. Meanwhile overhaul all your hives and cut out all of the worms and cocoons, and do a regular cleaning-up; then follow it up until the young Italians get out and take the job off your hands. Probably

the moth-worm has been allowed to develop to an unusual extent in your locality. Get other bee-keepers around you to turn in and help get rid of them. A very little earnest work every few days will get them entirely out of your hives and out of your apiary. We had lots of experience along this line, years ago, before we had Italian bees. See editorials.—Ed.]

### PERFECT COMBS WITHOUT FOUNDATION SPLINTS.

**Foundation in Brood-chambers Should be Drawn Out Only by Weak Colonies; the Super the Proper Place for Comb-building in Strong Colonies.**

BY G. C. GREINER.

Whenever the subject of foundation-splints has been discussed in our bee-periodicals I have been wondering why it was necessary that these splints had to be used at all. Mr. Green's article on page 562, with its various theories and suggestions, gives this matter a new impetus, at least with me. It induces me to offer a few remarks on this subject. I do this, not for argument's sake nor to invite any controversy. I have no time to waste for that purpose, but I wish to present a few facts along this line.

After reading Mr. G.'s article I examined a dozen or more drawn-out combs from the brood-nests of as many different colonies and the same number of drawn-out combs from my extracting supers, but failed to find any stretched combs with elongated cells, as Mr. G. describes. I knew the result quite well before, but I did it to make doubly sure I did not misrepresent or make false statements. It does not seem possible to me that different localities and climates could produce such contradictory results; but I am convinced that the difference is all in the management.

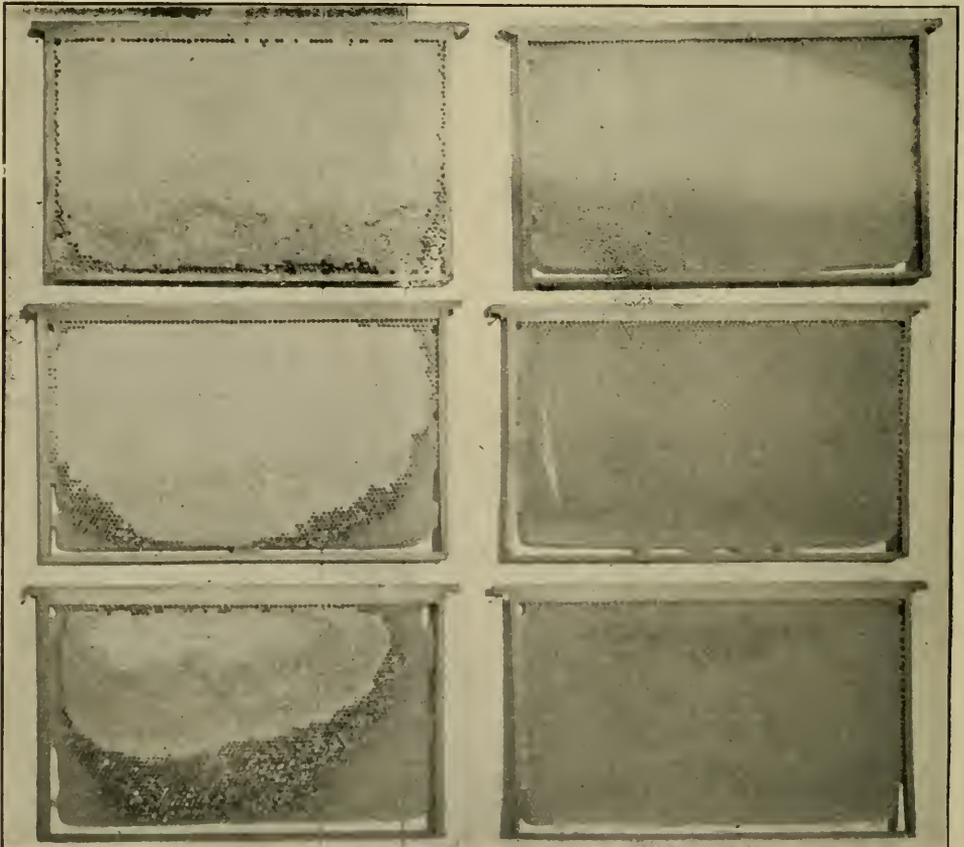

I have, during the last ten or fifteen years, used more or less foundation yearly; and this last summer, being a little short of extracting-combs, I again had 25 lbs. transformed into combs, and, strange as it may seem, there is practically not a sagged comb nor a stretched cell in the lot. I use, both in brood-chamber and extracting-super, what is called the Jumbo frame. Being 10½ in. deep in the clear it is probably the deepest frame of the flat pattern in use. Then I use full sheets of foundation 16 in. long by 9¾ wide, supported by three horizontal wires. This arrangement, according to Mr. Green's opinion, should give foundation the best chance to sag and produce the dreaded elongated cells; but it does not in my case, and why? I don't know that I can point out the exact cause, but here is my way of using foundation:

With the exception of a little experimenting years ago, when the use of full sheets of foundation in the brood-chamber was in its experimental stage, I have always strung my wires as tight as the wire and frame will bear. They fairly sing; and to produce this condition I use No. 28 wire. No. 30 wires would

not hold together under my treatment. They would snap off with every frame I handled. The directions for slack wiring to allow for the inevitable sagging, which Mr. G. cites, are contrary to my many years of experience.

Next I use medium brood foundation only. When we were advised to use light brood foundation in the main frame on the ground that it is more economical than the heavier kind, giving more square surface to the pound, I also experimented quite a little in that direction; but one season's experience satisfied me. It was buckle and sag, and sag and buckle all through the season, and I came to the conclusion that it would be poor policy to economize in one direction and then lose double and triple in another by being annoyed by the detrimental effects of elongated cells next to the top-bars. Mr. Green has plainly stated the results on this point.

Another feature that may have some bearing on the no-sagging inclination of my foundation is this: I never fill my frames in cold or even cool weather, but wait till later in the season until about the time when I want

Foundation, when built out into combs by Greiner's plan, results in perfectly straight combs, even though only three wires are used in a Jumbo frame.

to use my frames. It frequently happens that I fill a few dozen frames in the forenoon and use them in the afternoon. The weather is generally at its best in regard to temperature about that time. The honey-house in which I do this work is often as hot as an oven, to use the phrase, and foundation handled under these conditions has stretched about as much before it is put in the hive as it ever will or can thereafter.

Furthermore, I manage as much as possible to let my weakest colonies do the drawing-out. The excessive heat in the brood-chamber of very populous ones, together with the heavy load of bees, might possibly cause some sagging; but I aim not to use such colonies for that purpose. If I am compelled to use foundation with strong colonies I let them draw it out in the extracting-super, where sagging or stretching is not so likely to take place.

But, say what we may, all our theories and suggestions are of little value unless we have some show of facts to sustain them. As a proof that all I have said and claimed in the foregoing is based on a pretty solid foundation of facts I herewith present to the readers a photograph of a variety of combs which were drawn out from foundation last summer. They are not selected to favor my argument; but I have taken about the first ones I ran across.

The three combs on the left are more or less full of honey, and capped. On account of the cappings the shape of the cells is not readily discernible; but the dark streaks between the rows of cells can be plainly seen. They are as straight as a chalk-line when being snapped. But there is another proof that the foundation has not sagged. The space between the lower edge of the foundation and the bottom-bar of the two lower combs is as nearly even, clear across the frames, as it was the day the foundation was put in. Wouldn't this space be a little contracted in the middle if the foundation had sagged, and had caused elongated cells next to the top-bar?

The second or middle row contains empty combs used in the extracting-supers. They are now cleaned out by the bees, and show the shape of the cells very plainly. It takes more than ordinary mechanical skill to detect a difference between the shape of cells on these combs and the original impressions on the foundation on which these combs were built.

The manner of fastening the foundation to the top-bar may not have any bearing on the sagging question, and it may. I never fancied the groove-and-wedge plan very much, but did it in the old-fashioned way by running melted wax on both sides along the joint. After the joint is "soldered" up on one side, a much better job can be done on the other. Undoubtedly the wedge plan will do the work a little faster; but if we have the right tools, have our wax at the right temperature, and have once acquired the knack of doing it, frames can be filled at a very fair rate. This point can not be dis-

puted. While the running-on wax strengthens the joint, the pressing by the wedge weakens it.

La Salle, N. Y.

[At the time Mr. Greiner wrote, he was doubtless unaware of the fact that he was confirming the position taken by W. Z. Hutchinson, in the *Review*, that *medium* brood foundation and horizontal wires drawn taut, or until they sing, solve the problem of the sagging in the foundation and a consequent buckling between the wires—solve the difficulty of elongated cells near the top-bar and filling the same with drone brood.

But the question that still remains to be settled is this: Whether the use of *light* brood foundation and *more* horizontal wires or wooden splints, *a la* Dr. Miller, would not be cheaper and just as free from the objectionable sagging. It is our opinion that they would. Although we do not know positively, we are beginning to think that more strands of horizontal wires drawn taut, and *light* brood foundation, will not only be cheaper, but give us combs that will be vastly stronger than those supported by splints or by three horizontal wires. It may take more time to put in the extra wires; but when one is at the job the actual increase is only very small.

The melted-wax plan of fastening foundation to the top-bar as described by our correspondent is satisfactory in the hands of one who knows how to use it; but it is far from being that in the hands of the average person or novice. For all such the double groove and wedge is preferable. Indeed, it is quicker, better, and much neater for even the expert.—ED.]

### SHIPPING BEES IN POUND AND HALF- POUND PACKAGES WITH- OUT COMBS.

The Possibility of Shipping Bees Without  
Carrying Disease.

BY E. R. ROOT.

Some twenty-five years ago there was quite a business in selling bees in pound packages; but owing to the difficulty of delivering them alive to destination the business was given up, and from that time on until very lately bees have been shipped out only on combs. In late years foul and black brood have become so prevalent over the country that it seemed desirable to try the old-fashioned plan of shipping the bees without combs in order to avoid entirely or at least minimize the danger of carrying disease. Foul brood is transmitted mainly through combs, honey, and brood. If these three are eliminated in shipping bees and queens, the chance of transmitting disease, even from an infected colony, would be very slight. For the last year or so, we have been trying the experiment of shipping combless and broodless bees in little light wire-cloth packages all over the United States; and by chang-

ing the package somewhat, and by giving the bees a good feed of syrup just before starting on their journey, the loss during shipment has been almost entirely eliminated.

It occurred to us that if we took the old pound package of years ago and placed therein a series of slats so that the bunch of bees would have something on which to cluster without having to hang to each other, as in a swarm, one difficulty, at least, could be overcome, for in the old pound cages there was no form of support except at the top and sides. The consequence was that the bees were obliged to cling to each other anywhere from two to five days continuously, depending on the length of the journey. This, it seemed to us, caused unnecessary bodily strain on the bees. As we wished to avoid the use of combs for the reason named, we made artificial supports of sawn slats that answered in lieu of a comb; then after putting the bees in the cage, and just after they start on their journey, we give them a feed of thick syrup—enough to fill their sacs full. This renders it unnecessary for them to draw on the queen-cage candy already in the cage; for we calculated that the supply of syrup in the honey-sac of each bee would furnish a form of sustenance that would be safer and better than queen-cage candy, which, to say the least, is an unnatural food.

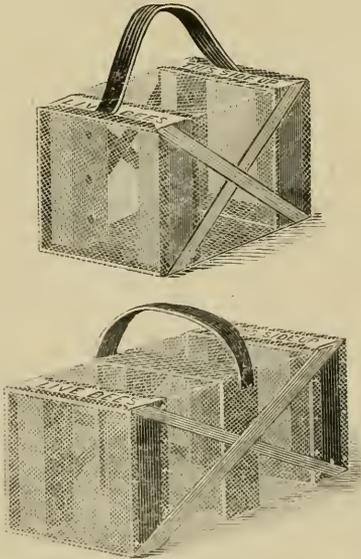

FIG. 1.

The form of cage which we use is shown in Fig. 1. The illustration, however, does not show the series of slats running lengthwise through the cage, and on which the bees hang for support while *en route*.

The question may be asked how the bees are fed through the wire cloth. This might be done in several ways; but the plan our apiarist adopted was to paint the syrup around the wire cloth until the bees had

taken up a liberal supply for the journey. They could be fed another way by inverting a Mason jar containing syrup covered with cheese cloth, and placing the jar and cloth, when inverted, on the wire cloth. But this would be a slower process, and would be no better in the end.

It may be interesting to the reader to know how bees are prepared for shipment in such packages. In the first place we have a wire-cloth swarm box capable of holding anywhere from six to eight pounds of bees. Through the top of this is a square hole large enough to admit the mouth of an oblong tin tunnel, which is of such shape and size that a frame well covered with bees can be shaken in it; and the bees, as they fall off, slide down the smooth surface of the tin into the swarm box below. One or two frames may be shaken from any particular colony. If we expect to put up a dozen packages we may shake some four or five different colonies, one, two, three, or more combs as the hive can spare. But the beauty of putting up bees in this form lies in the fact that we are not obliged to take them *all* from one colony; and, as we shall show, the queen to go with each package may be taken from an entirely separate colony or nucleus. When shipping bees on combs in the nucleus form it is necessary to take both queens and bees from one hive; but the bees and queens in pound packages may come from half a dozen colonies. In well-regulated apiaries there will always be a few colonies that can spare a few bees without detriment to their brood better than others; accordingly, when we fill up this swarm box or wire-cloth cage we draw from those stocks that can best afford the bees.

But perhaps the reader may ask how we keep them from fighting; and then if we take a queen from one hive, and the bees from two or three others, how we prevent their killing the queen. All this is very simple. After the requisite quantity of bees has been shaken into the swarm box, as shown in the different views of Fig. 2, the tunnel is lifted off and the opening closed with a slide. The bees are then put away in a cool room and left there over night. In the meantime a Mason jar containing sugar syrup is inverted over the wire cloth of the swarm box so the bees can take syrup through the night. The next morning this box of bees is taken over to the workshop and placed beside the various pound cages that are to be filled with bees. One of the cages is placed on a pair of scales. The bees are given a jouncing on the floor so they will be dumped in the bottom of the swarm box *en masse*. They are then scooped up by dipperfuls and dumped in the cage until the dial shows one pound or half a pound, as the case may be. The cover of the cage is then put on, when another package is filled in a like manner, and so on until all or nearly all the bees from the aforesaid swarm box are put in various packages. The next operation is to take the queens one by one from as many nuclei of the grade and price required, and, by lifting the wire-cloth covers at one corner, run them in one by

Fig. 2.—The method of shaking bees into a swarm-box preparatory to putting them in pound cages without brood for shipment.

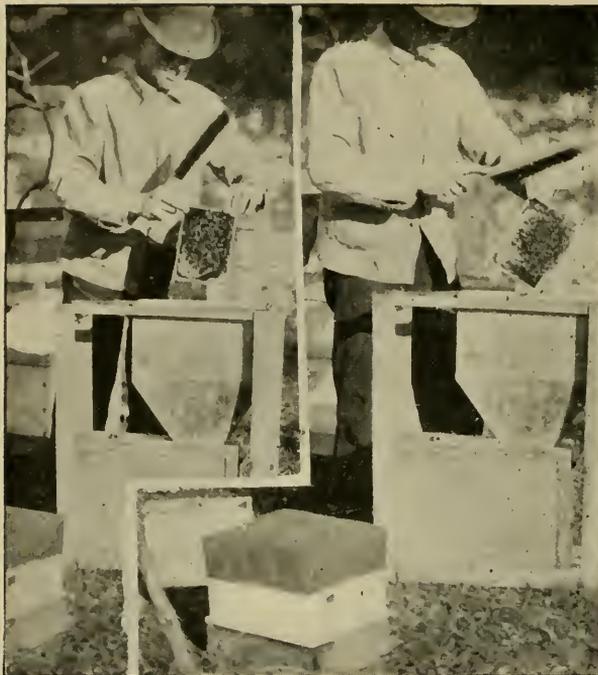

Fig. 3.—Shaking bees off the combs of baby nuclei late in the fall for the purpose of strengthening weak colonies in the same yard.

one—that is, one queen in each pound package.

The last operation of all is to dip a brush or rag into thick syrup and spread a thin film over the wire cloth. Care should be taken not to give them too much. If wire cloth is left dauby they will not go through alive.

Now, then, to answer the question why the bees do not fight or kill the queen. When bees are shaken into a box and made queenless, combless, and broodless, and kept confined over night, and fed sugar syrup,

they will be in a mood to accept *any* queen; and then, moreover, when they are shaken from several *different* hives, the colony odor is destroyed, and the absence of the queen, of brood, and comb, makes them fairly cry for something; and when that something is in the shape of a fertile queen she is accepted readily because of their dire distress.

Our Mr. Pritchard believes the mixing of *several* lots of bees has a tendency to make them more kindly disposed toward the queen, or to stay in a new location, than when all come from one hive; but our Mr. Bain thinks this makes no difference—that it is *confinement without comb or brood* that destroys their colony spirit, or that spirit that would resent the placing among them of a strange queen.

#### UNITING BEES IN THE SPRING OR FALL.

At the close of queen-rearing, perhaps in the fall, we usually have a lot of baby nuclei containing a few bees. It is impracticable to unite them in the ordinary way, and much less to winter them as they are.

Last fall Mr. Bain shook or brushed the frames of these babies into the swarming-box as seen in Fig. 3. When the box was fairly filled he closed it up, put it in a cool place, gave its bees a feed of syrup, and left them over night. The next morning the box was taken around to a hive that was a little shy of bees, and jarred on the ground to get all the bees in the bottom. They are next wet down with water from a brush or broom to keep them from flying. He then took a dipperful or two and dumped them in the entrance. This was done in the cool of the morning—

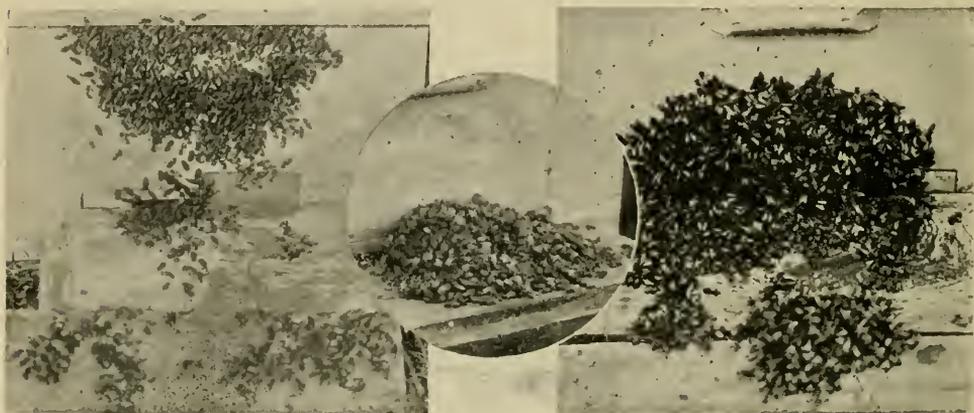

Fig. 4.—How bees are dropped from the swarm-box in front of entrances of colonies needing a few more bees for winter.

sometimes when it was so cold that the mercury was almost down to freezing.

In Fig. 4 it will be seen why the bees were bunched up and run into the hive. Strange as it may seem, they will all stay in their new quarters; and, what is more, they will take up with their new queen-mother. It comes to pass, then, that, instead of losing these babies as formerly, we can use them for strengthening up colonies in the same yard that are not quite strong enough to go through winter. The plan is so successful that the problem of uniting bees in the same yard, and making them stay in their new quarters, is practically solved.

It was Mr. G. M. Doolittle who, something over twenty-five years ago, advocated this plan of uniting. He found that, by shaking bees into a wire-cloth cage, and confining them in a cool place, he could do with them what he could not otherwise accomplish; but if we are correct he never went quite so far as to take the bees from a swarming-box like this and apportion them out among half a dozen colonies; but both Mr. Bain and Mr. Pritchard have proved that they can do this, although the plan pursued by the latter is slightly different from that of the former. Mr. Pritchard believes it is necessary to mix several lots of bees together, shut them up for an hour, wet them down, and dump them in front of baby nuclei which he wishes to supply with bees. Both Mr. Bain and Mr. Pritchard are agreed that *running bees through the entrance* is an important part of the procedure in making them stay in their new quarters. To put them on top of the frames will not answer.

In this connection Mr. Pritchard thinks that a thorough jouncing and shaking will put life and energy into loafing bees as almost nothing else will. Mr. Bain is not sure that this is so.

---

## A PROBLEM IN WINTERING.

BY F. DUNDAS TODD.

This is the story of a failure, of a two-thirds loss in a mild climate, but of an exceptional winter in this respect when, for about ten days in January, the thermometer was near zero while a very strong wind prevailed, and then followed a decidedly cool spring with the temperature daily reaching almost to the flight-point, but rarely attaining it. Theoretically, wintering in such a region as Vancouver Island should be a problem of easy solution, and some years it is so; but there are others when the losses are very severe. Again, different men have different experiences in the same season. For example, my nearest bee-keeping neighbor lost 30 per cent; the next, half a mile away, 60 per cent; another near him, 7 per cent; one four miles away, 50 per cent, and much the same way with others to whom I have talked.

To show still further contrasts, two years ago one bee-keeper, in packing his bees for winter, after putting in the material for one

hive in an empty super above, forgot to put on the cover. It was a mild winter, only one morning's frost, and that was in March; but there was the usual winter's rain. However, the hive came through swimmingly—not swimming—the bees apparently enjoying the luxury of two entrances, the extra one, of course, being above through the packing. But in the same season an old-time and very good bee-keeper not a dozen miles away lost eleven out of a dozen hives, supposedly through honey-dew.

The most interesting feature about a failure is its cause, and that is the hardest thing to locate. Looking at the facts in the first paragraph, an easy-going mind would instantly say "season," and let it go at that. But in the midst of so much failure there are successes to be accounted for, and so it is our business to eliminate, as far as we can, the common factors, then duly consider the differences so that we may learn the secret of success. For almost a year I have gone over, hundreds of times, every detail of my own management, considering nothing as too trifling or unimportant compared point by point with other bee-keepers, and feel I have narrowed the problem to two propositions, perhaps only one, and I want to submit them to readers of this magazine for their consideration, and perhaps get definite decision as to their merits.

First as to hives. As readers already know, I at present am experimenting with the divisible hive, and, as far as possible, have transferred all my purchases into that style; but in the fall of 1908, out of 20 hives packed for the winter, two were eight-frame Langstroths several years old. The other 18 consisted of 6 colonies in double divisions; 12 colonies in single division, each division containing eight shallow extracting-frames.

As is the custom here, the hives were wintered on the summer stands, but they were wrapped in tar paper—a precaution supposed to be unnecessary. The bottom-boards had 1 $\frac{3}{4}$ -inch rims, the entrance being filled with a block of wood in which was cut out a smaller entrance  $\frac{3}{8} \times 3$  inches.

I had started with nine hives, of various styles and ages, but had transferred in July and August to the divisible frame, too late as I afterward learned, since the honey-flow stopped before the middle of July, and there was no fall flow. In the middle of July I had requeened five hives by young queens from one breeder, and a month later I got a dozen queens from a different breeder, and so had 17 young queens and 3 old ones. After the final transfer I fed hive syrup to each every day to encourage wax production and brood. In the middle of September I proceeded to feed up quickly, and by the 20th every hive had at least 25 lbs. of stores on hand, every colony being actually weighed so as to make sure. Two months later, just before starting on a trip to the Atlantic States, I weighed several of the hives again, and found an average loss of four pounds, so I felt satisfied every thing was all right.

I got home Dec. 31, but no bees were fly-

ing as the weather was too cold. On Jan. 4 a cold wave struck this locality and lasted for about 10 days. About the 25th, bees were flying from most of the hives; and on the 27th, since a number were suspiciously quiet, they were examined and found to be dead, absolutely without honey and pollen. The others were glanced into, and found mostly to be on the edge of starvation. Then began a long weary fight with spring dwindling. In this I learned something about spring feeding in a cool climate. I tried feeding syrup from below, and discovered that the bees will not touch syrup so presented unless the air temperature is above 50°. Then I made candy, which was all right, and fed many pounds on top of the frames; but the quickest results I got was by giving soft brown sugar, Demerara or Porto Rico, in a frame affair set in the hive to one side of the brood-nest. Had I had a Doolittle feeder I would have tried it. But the bees needed pollen as much as sugar, and this I could not give them. For weeks the thermometer never rose above 48°, and, though willow blossoms were plentiful from Feb. 22, the pollen famine continued until well into April. Often I wished Dr. Miller or some other bee genius would invent a method of feeding rye flour in the hive.

Here is the mortality record for the various styles of hives. Langstroth: Original number, 2; died of starvation, 0; spring dwindling, 1; per cent of loss, 50.

Two division: Original number, 6; died of starvation, 0; spring dwindling, 3; per cent of loss, 50. One division: Original number, 12; died of starvation, 6; spring dwindling, 3; per cent of loss, 75.

All classes of hives, it will be seen, lost heavily; but a little explanation will modify these bald figures a little. The two Langstroths had stores of honey, even at the end of March. On March 18 one was in good enough shape to tempt me to put a weak hive on top, and a week later I found the queen in the upper division had begun to lay. April 2, flight looked very scanty, so I examined the lower division and found a big heap of dead bees on the bottom-board—no bees on combs, and not a scrap of pollen in frames; but there was about 2 lbs. of honey. On combining by the Alexander method I put wire netting above the excluder for two days, and had fed above a pint of syrup every night for a week. In other cases I had found this method seemed to work all right.

The story of No. 23, a double-division hive, is worthy of record. It was rather familiarly known as "skiddoo," and almost "skiddooed;" but now it is called rather profanely "resurgam." Feb. 11, seeing no flying bees I examined the hive and was astounded to find a lot of apparently dead bees without a scrap of stores, either honey or pollen. I picked up frame after frame, each covered with dead bees—not a tremor of leg or wing being visible. A few fell into the hollow of my hand, and, acting on impulse, I breathed on them for a few minutes, then I saw a few legs move a little. I hunted for the queen,

and, finding her, tried the effect of breathing on her majesty. I fancied one leg quivered a little, so I replaced the combs in the hive, placing the queen with a loose handful of apparently dead bees on top of the frames. I put the hive on top of another colony with wire netting between. Lastly I mixed honey with water, and trickled over the bees and combs, then put some candy on the frames.

I was not hopeful of any good results, but next day I was much astonished to find the bees very much alive; and two days later the hive was replaced on the old stand. It simply kept alive until March 27, when I found a little brood; so I gave it a little sealed brood to help along with young bees. April 7, having bought some more hives I put it at the top of one of them for three days, then moved the old hive to a new stand. It advanced right along, and by the end of the season no hive had more honey-dew in its combs than that had. My notebook says 40 pounds.

But for a happy thought, No. 23 would have been among the dead, and the percentage of deaths of the two division hives would have been 66—that is, nearly equal to the single-division colonies.

My friend Mr. Russell wintered his hives pretty much as I did; and in comparing notes we arrived at these general conclusions:

The one-division hive was as successful as the two-division one.

A deep-rim bottom-board was as successful as a shallow one.

Since one of the oldest bee-keepers in this locality has frequently wintered on 12 lbs. of stores, and once on as little as 10, our 25 lbs. per colony ought to have been sufficient.

Our best results, but not numerous enough to justify generalization without other evidence, were with the hives that had not been transferred.

We could not blame the strain of bees; for in my own case two out of three of the old queens died, all the first importation of young queens, and five out of the dozen of the second lot.

We believe there was no honey-dew in our hives. I had fed an average of 15 lbs. of sugar to each.

The almost complete absence of pollen in the frames, although much was carried in during the fall months, led me for a long time to think that the young queen in the mild weather of November and December had bred freely, and so used up the stores. The bountiful supply of dead bees on the frames still further confirmed this suspicion. But in the course of my reading I stumbled on another idea which, the more I think of it, appears to be the best explanation of my failure in wintering. It is found in "A Modern Bee-farm," by Simmins, who emphatically advises that only old brood-combs should be used for wintering, insisting strongly that the cocoons and other matter in the combs prevent the conduction of heat, whereas pure wax, as in new combs, permits the heat to disperse rapidly, and the bees soon

use up their stores to generate sufficient warmth.

The only complete sets of old combs were in the Langstroth hives, and these were the only ones that did not need to be fed. After noting Simmins' warning I examined all the combs in the dead hives and found that very few of them had been bred in—in fact, they were hardly travel-stained. This disposed of the breeding-up theory.

So, after long consideration I am of the opinion that new combs is the real explanation of my failure in wintering; but I will gladly welcome any evidence to the contrary, for I am well aware that some bee-keepers advise the frequent discarding of old combs in favor of new; but I have not in the course of my reading found any one who recommended that bees be wintered on combs that had never been bred in.

For the winter of 1909 I have tried, as far as possible, to have the bees on old combs, though not as completely as I would like, as I transferred practically all my new purchases, and, besides, have had to contend with the additional handicap of a blank season. But I am wintering six Langstroths with undoubted old combs, and am awaiting the results with considerable interest.

Victoria, B. C., Oct. 20.

## BEE-KEEPING NOTES FROM TEXAS.

### A Series of Articles in Answer to Numerous Enquiries.

BY LOUIS H. SCHOLL.

#### INTRODUCTORY.

Letters by the score, regarding Texas as a honey-producer, and many other questions relative to bee-keeping in the great Lone Star State, together with several requests from many, and, lastly, a request from the editor, have prompted the writing of a series of articles for GLEANINGS for 1910, with the hope of answering all these enquiries as far as it is possible to do so, and fulfilling the requests so often made.

Texas has grown, is growing, and will continue to grow, not in area, for she is big enough in that respect, but in every thing else imaginable, for she is making greater strides now than ever. In this, bee-keeping must be included, for that, as every thing else, has progressed until now it has placed the great Empire of States in the lead, ahead of any other in the Union. We are not saying these things to boast, nor have we an ax to grind or something to sell, but merely because they are facts for which we have been asked, and to give the information sought by so many.

While many of the localities are already taken up and some of them overcrowded, to the detriment of the bee-keepers, there are others that are entirely unoccupied. To prevent the influx of new comers continually settling in parts already occupied, and aiding in a better distribution of such into new

and better localities, for the benefit of all concerned, shall be the aim, in part, of these papers, which will follow in rotation as space permits. Besides information about Texas and the bee-keeping localities, articles will follow on subjects like the following, which should be of interest, not only to those who are interested in Texas bee-keeping, but others as well, as these will embrace methods and management that are applicable to other localities as well as in Texas and under Texas conditions. These will be mostly formulated after our own extensive work with 20 apiaries scattered from a few to several hundred miles from the center of operations, and with an experience in this State of nearly twenty years of bee-keeping.

The series that will receive attention throughout the present year are about as follows: "Texas, what she is as a honey-producer;" "The widely different and varying localities in Texas;" "Some of the advantages of Texas over other honey-producing States;" "Something about Texas honey-yielding plants;" "The kinds of honey produced in Texas, and why;" "Bulk comb honey and its extensive production;" "Texas from the standpoint of queen-rearing;" "Why the ten-frame hive is most used;" "The advantages of the divisible hive;" "Extensive out-apiary management;" "Getting the most for the honey crop;" with perhaps a few changes as needed.

By the aid of pictures and the use of charts and drawings it is our intention to make the reading-matter not only the more interesting but plainer, so as to be easier to understand. We shall be brief, yet try to cover the ground; and it is hoped that the readers who are interested in these notes from Texas will not only assure themselves that their subscription is kept up but will direct others of whom they know, who are or might be interested in this series, to subscribe for these numbers for the entire year, and thus not miss any of the copies. We call attention to this matter only so it may save others writing to us with numerous questions on these subjects that will be fully discussed in GLEANINGS during the year. It has been our desire to call attention to this series for that reason, and therefore this introductory has been written.

New Braunfels, Texas.

## OUR EARLIER BEE-KEEPING.

### Trials and Tribulations; Use of Comb Foundation; our Section-supers, etc.

BY F. GREINER.

My first real experience with bees dates back to the year 1872. When I had hived a swarm with the help of an old soil-tiller, and did it successfully, and without any special protection, my enthusiasm was kindled, and I began to think that I had the stuff to make a regular professional bee-man. The hives then in use here were box hives. No one in these and many other parts had even

heard of a frame hive. I remembered from my boyhood days a frame hive in my grandfather's house-apiary; for Baron von Berlepsch, simultaneously with father Langstroth, had constructed a frame hive already in 1856; but I had not yet formed an exact idea of the frame, the bee-spaces, etc., even after reading a bee-book of Dzierzon; and when I bungled up a sort of box hive with frames it was any thing but perfection.

In 1875 I saw the first properly constructed frame hive, and I, with my older brother, G. C. Greiner, well known to the readers, built several hundred such hives in the spring of 1876. Unfortunately, GLEANINGS had not yet found its way into our hands, and we were, in a measure, groping in the dark.

At the centennial exposition in Philadelphia, 1876, I saw the first sample of comb foundation. The article was rather inferior as compared to what our manufacturers turn out to-day with their complete machinery, their superior methods of cleansing and purifying wax, etc., but it was a long way ahead of no foundation at all. Up to that time, and for one or two years after, we had to (or did) get along with naturally built comb as starters in our honey-boxes and with wooden comb-guides in the brood-frames. Many a time we were forced to take old comb and cut it nearly down to the septum so as to serve us in our comb-honey supers. We had to be on the lookout for new comb constantly wherever an opportunity offered. During fruit-bloom was a good time to have strong colonies build us comb of the finest kind for starters; but this required close watching, and the hives had to be opened often and the comb cut out in order to get the start of the queens. The younger beekeepers, who have always had comb foundation to use as starters, both in brood-frame and super, would now consider it a great hardship if they had to get along as we did in those times.

However, we produced very fair honey, even under such adverse conditions. We were then using a nailed two-pound box, which was glassed on both sides after being filled by the bees. The package—wood, glass, and all—was weighed up and sold as honey. It was certainly not a losing game to put on the glass. Sometimes the sheets of glass were very thick and heavy. We never ordered such heavy glass, and our conscience troubled us not a little for hoisting this on the unsuspecting customer. We produced, during the years 1875, '76, '77, till 1885, many tons of comb honey, of which every box was glassed, and the gain thus made was considerable.

In 1877 we were only just beginning to use separators as an experiment. Tin separators were used by A. I. Root at this time and previously; but we had not found it out, and we were trying wood as the more congenial and natural. James Heddon and others argued that wood could not be used successfully as a divider; but in all of our trials it proved a success. We constructed several different

styles of supers with wood separators, for our open or undivided super did not please us, although we had little trouble in crating all the honey we produced with the help of them.

It is sometimes claimed that it requires more skill to produce good honey without separators than it does with them; but in view of the fact that we for several years, as beginners at that, successfully produced comb honey by the ton without separators—yes, and also without the auxiliary of comb foundation, this contention is without sufficient support—nay, it seems to me the greater skill is required to produce comb honey in our modern divided and sub-divided and cross-divided supers.

Before adopting a super which satisfied us during this earlier period, many of different styles were studied out; and after trying them we discarded them till we hit on the wide-frame single-tier super. Just about this time GLEANINGS came into our hands for the first time, and we found that A. I. Root had a double-tier wide-frame super already in use for several years. With this fact before us our confidence in our single-tier super increased to such an extent that we speedily changed all our stock of supers into this style—something which I never had the slightest reason to regret, although manufacturers have abandoned their wide-frame (double-tier) super for such of other constructions. The most or all of these newer supers do not protect the tops of the honey-boxes, and they at times become badly besmeared with propolis before being ready to be removed from the hives. The T super is the simplest and most inexpensive of all the supers before the public. It neither protects top nor bottom of the section boxes.

To be fair, I have given nearly all of the different styles of supers a trial. With me those parts of sections which are unprotected—in other words, are not covered up by either the bottom-bar or the top-bar—the sides of the sections being protected or inaccessible to the bees in all kinds of supers—have often, if not usually, become besmeared with bee-glue to such an extent that I could not properly clean them with a knife. I consider this a serious enough fault to condemn all such supers as leave either the tops or the bottoms of sections exposed to the bees; and I have gradually worked them over into wide-frame supers with the exception of some thirty T supers, which so far have escaped, although they are not expected to be put on the hives again in their present form. By mere accident two or three were put on last summer, and were filled also. It was a singular occurrence that a case of honey which I took to one of our groceries a few weeks ago came from one of these T supers. I had forgotten it; and when I opened the case I was greatly mortified to find such dauby-looking boxes. I believe I take at least as much pains as the average beekeeper in cleaning up my honey, and I remember very distinctly having used more "elbow grease" with this lot than with my

other honey, even using sandpaper; but to make a respectable lot of it was impossible. I had to give it up.

In favored localities, and with a good honey-flow making it possible to get the section honey off the hives inside of three weeks, reasonably clean honey can be and is being produced; but in my locality, and perhaps with my faulty management, I need something like a wide-frame super. Such a super has a further advantage over all other supers inasmuch as it provides that Pettit bee-space, not only at the sides but also at the ends; and the better filling of the end sections in the wide frames over those produced in T supers or the like is unmistakable.

The average bee-keeper is satisfied with such hives and other appliances as the supply-dealers see fit to offer; and if in any way they can get along with them they continue their use and say nothing. The more exacting go to work and make their supplies to suit their own notion.

I note with satisfaction that, in the catalog of 1909, a wide-frame super is listed, and I hope many will avail themselves of this opportunity and give them a trial.

During the earlier years of our bee-keeping we were rather unsuccessful as to wintering our bees. In the winter of 1880 we lost more than half of our colonies. We attempted to winter without protection (packing) on the summer stand. After some heavy losses we found that it was unsafe to winter bees thus outdoors in our climate. We succeeded quite well in wintering in cellars; also by packing our bees. My fifty chaff hives come through in good shape almost without fail each year. It makes little difference whether the bees are under sealed cover or whether a quilt is substituted under the packing instead of the inner cover or honey-board, as we used to style it. With ordinary winter supplies (stores) I little fear the winter. Only when our hives are crowded with honey-dew do we need to anticipate winter losses.

Naples, N. Y.

### ITALIANIZING IN SOUTH AFRICA.

#### No Foul Brood; Can the Disease be Carried by Mail?

BY D. S. VAN WARMELO.

We have in South Africa two well-known kinds of honey-bees that gather and store honey—the yellow and the black bee. The yellow bee looks very much like the Italian, but is smaller, and has a more pointed abdomen with the yellow bands less pronounced to the end. The black bee is, as the name suggests, dark in color, and looks quite different. Both kinds are very vicious, the black one taking the cake, but is, although smaller in size, the better honey-gatherer according to most farmers.

Before the Boer war broke out, in 1899, I kept, as a hobby, the yellow bee in a few

Langstroth hives in Pretoria, and have only since the war made a special study of bee-keeping, on a limited scale, however, as I would not be allowed to keep an apiary in the town, however big and secluded my place may be. But on this account I considered myself in a good position to experiment with Italian bees, and imported a few last year. I also got some from the government to experiment with.

Some colonies of the native yellow bee are wild, and so this race might by selection be civilized in the course of many years; but it would, judging by the absence of outward signs, take a very long time, as it would be difficult to judge, even if the offspring of a mild queen, whether she has mated, for instance, with the drone of the colony that had been artificially stimulated to rear drones out of season; and, besides, the bees of a colony may remain quite tame for many months, and one day sally forth and sting to death every living creature near their abode. Every year my fowls are stung to death by my bees, generally when I am not at home, through boys throwing stones at the hives, or by some other provocation less naughtily meant.

On account of this viciousness of the native bee, the importation of the Italian bee would be a great boon to us if, in other respects, it is as good as our bee in our climate. In winter in the Transvaal the nights are cold and the days warm with sunshine. To the Italian bee this difference in temperature seems to be perplexing; for on my return home this winter, after an absence of three months, I found the Italians weak, with hardly any brood; but the brood-chamber was stocked with honey, though not so much that not enough room was left for the queen to lay eggs; whereas the native colonies, instinctively knowing that there will always come in some honey from the eucalyptus-trees during winter, and also feeling the necessity of making up for the wear and tear of life, which in winter is great in a mild climate, had used up much of their stores in order to raise brood. This I consider the redeeming quality of our native bee, as I would rather feed a colony or leave it much honey than run the risk of losing it through insufficient breeding.

Last season I had introduced seven Italian queens by my own safe method, i. e., by tacking wire gauze over a queen-excluder, putting this on a strong colony and over it a brood-chamber with the Italian queen on combs with hatching bees. From these queens I reared several more which I either introduced by the Simmins pasting (direct introduction) method or reserved in nuclei. In order to avoid confusion I had cut the right wings of the imported queens and the left wings of the untested ones.

On my return three weeks ago I united the weak colonies and gave them all Italian queens mated with common drones, retaining three pure imported queens to rear from next season, when I shall, by the law of parthenogenesis, have only pure drones fly-

ing from all my colonies, twelve in number. In the summer, in December, last year, when the honey-flow ceased I was disappointed in the Italian bees casting out all their drones so that I had to abandon all hope of rearing any purely mated queens, not having time to rear drones artificially. This year I hope to continue my experiments, and, if successful, I may afterward be able to judge which bee is the better, and whether the Italian is likely soon to acclimatize and acquire, through experience and inheritance, those qualities that are essential in our country. If she behaves in the same way in her native land as she has done here this first year, then she has, besides her gentle nature, only one quality better than our bee—namely, of putting on a tremendous spurt to bring in the last drop of an ebbing honey-flow.

Langstroth made mention, in his book, of this quality of the Italian bee of filling the brood-chamber with honey, but did not state whether or how this drawback was overcome. I should be very much pleased to learn from the editor, or somebody else, what those men experienced who first introduced the Italian bee into other countries, and how they succeeded in educating it up to the customs of the adopted country.

We have no foul brood in South Africa. As the disease is, according to most books, in the honey-sac, the starvation cure being the most effective remedy there seems to me no danger of importing queens in traveling-boxes, as I have received mine, in the accompaniment of about 25 bees, provided every thing but the queen is immediately destroyed on arrival. Or do you agree with those who advise us not to import foreign bees?

Likewise, I should be very glad to be informed whether the governments of other countries appoint bee-experts who go about lecturing on bees, giving demonstration lessons, and generally teaching people how to work with bees. Such encouragement from the government would certainly tend to promote bee-keeping; but has it any drawbacks? Harmony, Pretoria, Transvaal, South Africa, July, 1909.

[It is probably true that Italians are more inclined to congest the brood-nest with honey than blacks. While for the production of comb honey this is a slight disadvantage, yet for the future prosperity of the colony it is an advantage. If, however, the modern methods of comb-honey production are followed there will be no great difficulty in getting Italians into the supers.

We do not believe that foul brood can be carried in the ordinary mailing-cage providing the precaution is taken to transfer the queen from the cage in which she is received to an entirely different cage for introducing. The only way of carrying infection would be through the honey used in making beecandy. Reputable queen-breeders in this country, so far as we know, make it a practice to sterilize the honey which they use for making queen-cage candy. If the party at

the other end of the line who receives the queen transfers her to an entirely different cage we do not see how the disease could be transmitted. Of course, as a further precaution the mailing-cage should be burned.

England sends out bee-experts to lecture on bees in different sections of the country. Just how much of the territory they cover we do not know. Something of this kind is done in other European countries. So far the United States has done nothing of this sort except that its experts in the Bureau of Entomology, Washington, D. C., sometimes go out to attend bee conventions, where, of course, they are called on to read papers. Some States of the Union send out foul-brood inspectors who not only give directions on how to cure bee diseases but furnish valuable information on the general handling of bees.—Ed.]

### QUEENS HATCHED ABOVE AN EXCLUDER.

#### A Good Plan for Keeping Surplus Queens.

BY A. J. BURNS.

Last fall I put some thirty or forty ripe queen-cells in as many upper stories, provided with an upper entrance with a division-board between made of very thin boards with a three-inch hole bored through on each side of the center about midway between the ends, and covered with excluder zinc. Of the whole lot I got only three queens fertile; the rest disappeared, or I found them dead on the division-board. A number of others disappeared similarly. I then began to watch for the cause. I saw nearly all the young queens just after emerging, so I know they had a fair start. One day I saw a young queen crossing one of these openings when a worker came up from below and seized her and almost instantly stung her. A few spasmodic quivers and she was dead. The queen below was less than a year old. In the light of Mr. Beuhne's experience, page 1062, Sept., 1908, perhaps if the queen below had been three years old or over it would have been different; but I do not often have queens as old as that. I then tacked a piece of wire screen on the under side of the opening, and nearly all were fertilized; however, by this time I did not have many queen-cells left, and it was too late to start more.

I found these queens to come in most opportunely later. Half a dozen or more colonies became queenless through various causes. I took one of these stories, bees and all, where there were two queens and changed places with one of the stories of the queenless colony, taking the story with the most or least honey, or most or fewest bees, as seemed advisable under the circumstances; placed a sheet of paper between the strange bees so they would mingle gradually, and all went well.

San Diego, Cal., Nov. 30.

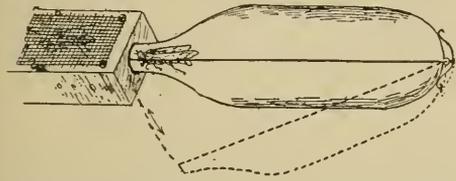

## HEADS OF GRAIN FROM DIFFERENT FIELDS

### HONEY COULD NOT BE FILTERED THROUGH CHARCOAL.

On page 674 Mr. H. D. Tennent suggests that bone charcoal might lighten honey-dew and improve its flavor. In order to benefit by the bone-charcoal treatment the honey would have to soak right into the pores of the boneblack and percolate intimately through it. I do not see how such a heavy syrup as table honey could possibly do this. I never worked as a chemist in a sugar-house using boneblack (beet-works use sulphur fumes instead); but I see in some text-books that the filtering is done on intermediate syrups, say 30 or at most about 50 per cent solid matter. Honey at about 80 per cent would have to be diluted by more than its volume of water, and filtered hot. I am afraid it would not be possible to bring it back to 80 again without boiling, and then the product might get darker in color than it was in the first place. Also, if boiled, the honey would show a reaction for fural, and this might bring it in collision with the pure-food laws.

### A FASTER WAY OF CAGING BEES.

It seems to me that time might be saved in putting bees into queen-cages by using a little arrangement something like the one shown below. The bees could be allowed to crawl in from one or two while the oper-

ator would be brushing some more into another from the proper nucleus. If a beginner had just one he would be happy in relieving his clumsy fingers from the strain.

BEN P. EDGERTON.

Hicksville, Ohio, Nov. 4.

[Your arrangement for catching a lot of bees, and running them into a cage, looks, on first thought, as if it might work very nicely. Your idea seems to be to put the bees into a dark inclosure, assuming that they will go toward the light and into the cage; but in actual practice we doubt very much whether they will do this. Of course some of them would go into the cage, but others would remain in the wooden bottle, so to speak. While we never tried it, we doubt very much whether for average work a queen-breeder could put up as many queens with this arrangement as he could in the old-fashioned way, picking up the queens one by one, and putting them into a cage as illustrated recently in these columns. The hand-pick method is sure of results.—ED.]

### ITALIANS DYING FASTER THAN THE BLACKS.

I introduced Italian queens to some of my black bees last summer. I examined them late in the fall, and they had plenty of honey to carry them through. In fact, the Italians had more honey than the blacks. I keep my bees outdoors all winter, as we don't have very cold weather down here.

The coldest weather we have had this fall and winter was just cold enough to freeze water so ice would be about a quarter or half an inch in thickness; and every time these little cold spells come, which last from one to three days, I can find from half to a handful of dead bees among the Italians, and none at all among the blacks.

### WHAT IS THE BEST PLAN TO KEEP DOWN INCREASE?

I have nearly as many bees as I want, and I wish to adopt some plan to keep them from swarming. The above two subjects are some I want to have your ideas on; and any thing you give me on the same will be appreciated.

### TOBACCO-BLOSSOMS NOT INJURIOUS TO BEES.

Mr. J. A. McKinnon, page 787, Dec. 15, wants to know whether tobacco is harmful to bees. I live in the tobacco belt of North Carolina, in Granville Co. Tobacco is the principal money crop, and it is grown here on

a large scale. I have noticed, time and again, when tobacco-fields were in full bloom with thousands of blossoms, and I have never yet seen a bee gathering nectar from them. For this reason I don't think it was tobacco-blossoms that affected Mr. McKinnon's bees.

Tar River, N. C., Dec. 27.

J. Y. CREWS.

[Years ago some statement was made to the effect that blacks were harder than Italians. In 1879 we had something like 20 colonies of them among our Italians. We kept them to test them in comparison with yellow bees. They were inferior as honey-gatherers, mean as robbers, and no better for wintering, or at least that winter, as it was an ordinary one. There has been a sort of impression that black races of all kinds are more hardy than any of the yellow races. This is possibly true, as their native habitats are in colder climates, but not colder than the home of leather-colored Italians on the Alps of northern Italy and Switzerland. Any yellow bees bred for yellow color, according to our experience (and we tested a good many strains of them), will not winter as well as the leather-colored strains of Italians. It is possible that you may have had some of this too much inbred weakened yellow blood.

The best plan to keep down increase is too large a question to discuss fully here, and we would, therefore, refer you to the text-books, particularly our A B C and X Y Z of Bee Culture, under head of Swarming. If we were running for extracted, and desired no swarming, we would use ten-frame three and four story hives, without queen-excluding honey-boards. If we were producing comb honey we would use any standard hive, clipping the queen's wings, and give the swarm as it comes out on the old stand in another hive containing foundation starters. The parent hive we would place at one side, and at the close of the season we would put it on top of the hive of the swarm, of course taking away one of the queens.

With regard to the question of whether the nectar from tobacco-blossoms is injurious to bees, your experience would prove nothing, as you say the bees in your locality do not work on the blossoms. What we wish to know is the effect of tobacco-nectar on bees when they do work on the plant.—ED.]

### WHAT SHOULD A SECTION OF HONEY WEIGH?

On p. 591, Oct. 1, is an item on "scales for weighing sections," stating that all sections not weighing 13½ oz. should be put down as seconds. Now, will a 13½ oz. section, or even 14½, go for a No. 1 section? There are 16 ounces in a pound, in New York; then the section itself weighs about an ounce when dry; and if a customer is to get 1 lb. of honey it should weigh 17 oz. or else honey goes for 12 oz. to the pound. Please enlighten me, as I am a beginner. Most of my sections weighed 15 oz. when full.

### ARE THE GOLDENS HARDY?

Are the golden Italian bees as rugged and as good workers as the three-banded? They are very pretty; and if as good every way I should think there would be a good demand for them.

Johnsonville, N. Y., Dec. 20.

A. D. CASE.

[There is no advantage in having a section weigh more than a pound. Most dealers prefer to have a scant pound; and some even prefer to have them weigh no more than ten or twelve ounces. A full pound of honey at the present time runs anywhere from 18 to 25 cts. at retail. The average householder wants something he can get for about 15 cents.

Our experience with golden Italians (and we tested a good many strains of them winter after winter) is that they are not hardy in comparison with ordinary strains of Italians that have not been weakened by inbreeding. Our different apiarists who have worked for us have, time and time again, remarked that extra yellow bees that we keep to show to visitors are the first to die in winter if there is any mortality. While the ordinary strains would come through in fairly good condition the yellow bees would either die outright or be very much weakened before spring.—ED.]

### WHAT APPEARS TO BE POSITIVE PROOF OF THE VALUE OF BEE-POISON FOR RHEUMATISM.

Dr. Bonney says, page 784, Dec. 15, he had rheumatism after becoming immune to bee-poison. That is one side of the story. Let me give you the other one. I used to have rheumatism so bad that several times I was for a week at a time on my back unable to get up on my feet without suffering extreme pain. Since I began keeping bees I have been entirely rid of that ailment with the exception noted below, and I believe that my cure was due to the bee-poison; but the doc-

tor would not accept this as proof. He said it just happened so, or that the rheumatism was just ready to leave me. But I have a stronger proof in support of my belief. I broke my arm over thirty years ago, and once in a while I have had severe rheumatic pains in my wrist. Whenever that has happened (more than twenty times) I have gone to a hive, caught a bee, and made it sting me on the affected part, and in less than a minute the pain was gone. That remedy never failed me.

Lake Mills, Wis., Dec. 21. GUSTAVE GROSS.  
[The last incident seems to furnish quite positive proof of the value of the poison.—ED.]

#### MOLD ON HIVES IN A CELLAR.

We put 150 colonies in the cellar with ice, snow, and frost upon the hives. Some of the hives have white mold on the fronts. The bees have been in ten days, and the thermometer stands at 42 F. It was 30 the first day. The hives appear to be damp. I expect to put some lime in the cellar to slack and take up the moisture. What would you advise? IKE BARBER.  
Smithland, Iowa, Dec. 11.

[If your cellar is too damp, and especially if the temperature is down to 42, we would advise you to use a small drum stove and burn chestnut hard coal. A light fire for a few hours would dry out the cellar and raise the temperature to about 45. It should not ordinarily go much higher than that. If it should run up to about 45 without the stove, dampness on the outside of the hives would do no particular harm. If the temperature was 42 at the time you wrote, it would be our opinion that it might run much lower than this before the winter is over. If so, you might have some severe losses with considerable dysentery; for of all poor places to winter bees in, it is a damp cellar with a temperature running down to 40 or below.—ED.]

#### LIME TO PREVENT "WEEPING" OF HONEY.

I do not think it wise, usually, for amateurs to try to rush into print; but after reading Mr. Hart's "tale of woe," page 738, I am tempted to say that I am storing comb honey in a basement. It is dry, but there has been a little tendency to "weep," and I am trying the experiment of putting a few pounds of fresh lime under each pile of supers. I place a bottom-board on the floor of the basement, an empty super on that, some lime in that, then tier supers of honey right from the hives twelve or so high above the lime. So far as I can judge, the scheme seems to have some merit; and if it is new, perhaps some who are troubled with weeping honey would like to try the experiment also.

Billings, Mont., Dec. 10. C. M. CHAFEE.

[If possible some other place rather than a basement should be selected for storing comb honey, for the air, though apparently dry, is seldom dry enough. The letter below from Mr. Wilcox covers this matter pretty well.—ED.]

#### THAT "WEEPING" HONEY.

A few years ago, when I was producing comb honey largely I had some experience with the same trouble, page 738. If honey was stored in a room much cooler than the outdoor air, or one wholly or partly below ground, or if the room was very close, with little or no ventilation, that sweating or "weeping" appearance was almost certain. I have seen it in the supers on the hive where the colony was very much reduced in strength after the sections were finished and a spell of warm foggy weather followed. I always prevented it where I stored it in a well-ventilated chamber under the roof with a fire in the room below.

There is much difference in the thickness of cappings. That with thick cappings will not "weep" as soon as that with thin ones. I thought the cappings were made thicker by leaving the sections on the hive after they were finished; but of that I am not so certain. I think comb honey can be made thicker by good storage after it is off the hive, and I know it can be made very much thinner by bad storage.

Mauston, Wis., Dec. 15. F. WILCOX.

#### WHITE RATS DRIVE OUT GRAY ONES.

In your Dec. 15th issue is an article on how to get rid of rats. I was troubled with them, and secured a pair of white rats and let them run on the premises. I fed them at the shed where I kept my bee-supplies. They are not destructive, as I have left combs filled and foundation exposed, and they did not touch them. They drove out all the rats and mice on the place.  
Lebanon, Pa., Dec. 26. W. H. JONES.

#### WIRE CLOTH IMBEDDED IN FOUNDATION.

Having read the arguments pro and con in regard to fastening combs in frames by wiring or with splints, the idea suggested itself to me why wire cloth could not be used with a soft thin wire, and a mesh of about the size of a worker-cell, and milled right into the foundation at the factory. The size of wire and mesh best adapted could soon be determined by a little experimenting. It would be cheap and effective. It would not be necessary to have it the full width of the foundation sheet. One-third or half the width would certainly be enough. I think it would not cost much to try it. I never saw this idea mentioned before, so there is no patent on it.

Fredericktown, Mo., Dec. 13. J. BACHLER.

[Wire cloth such as you describe would be too expensive. Then, too, it would be practically impossible to run it through a mill as you suggest.—ED.]

#### HOW TO AVOID AFTER-SWARMS.

How would you treat a colony with a clipped queen that has swarmed and lost its queen, and the queen-cells hatching? I want to save absconding. The bees seem to have such a desire to swarm that most will leave if they are not divided quite small.

Canton, S. D. L. A. SYVERUD.

[After the prime swarm has come off from the colony there will be a number of virgin queens, and each one of these will be likely to lead off an after-swarm until there is nothing left of the old parent colony. After the first swarm has been cast, all cells should be destroyed but one. If the virgins are hatched they should all be removed but one. While this plan will not necessarily stop after-swarms in every case, it will go a long way toward it. For a further discussion of this subject see "Swarming" in our A B C and X Y Z of Bee Culture.—ED.]

#### UPWARD VENTILATION VS. SEALED COVERS.

Sealed covers should always be made from half-inch white pine. They should not be disturbed too late, for the bees should have them sealed before cold weather sets in. If bees are packed in chaff hives, as they should be, with a  $\frac{3}{8}$  x 8 entrance kept free from snow and ice, this entrance will take care of all ventilation required to carry moisture from the colony. Wild bees do not have absorbing cushions. Who ever heard of an absorbing cushion in a bee-tree? The moisture is taken care of by the entrance to the cavity. Bees will propolize all cushions where they can get at them; and since this is true, why do we put such material there? I have always used sealed covers—the tighter the better. I have not lost a colony of bees in wintering with sealed covers in 25 years.

Ashtabula, O., Nov. 6. THOMAS CLARK.

#### WINTERING ON SUMMER STANDS.

My hives are eight and twelve frame, also twelve-frame sectional. The latter I like better for many reasons. All except the eight-frame are made of 1½ red cedar, with flat covers of the same cleated on the ends. These are fitted snugly over the frames without packing of any kind. When the wet season arrives, the hive is blocked up in the rear as high as it will go without sliding off the stand. This allows condensed moisture to run down and out at the entrance without any falling among the bees. At the same time it makes a deep hive out of a shallow one, which is no small advantage. Do not hesitate to try it.  
Sonora, Cal., Nov. 11. A. V. HEROLD.

#### COLORADO GRADING-RULES ALL RIGHT.

Friend Trickey, of Reno, Nevada, says, p. 723, Dec. 1, "We must depend very largely upon the honesty of the producer. If he does not grade honestly and fairly, cut him out." Our Colorado rules do this to a T, and no one person or committee is called upon to do the cutting. Our rules saved us this year of light weight.

Platteville, Col., Dec. 13. R. H. RHODES.

#### SIZE OF BEE-SPACES BETWEEN SUPERS.

When one runs for comb honey, and has two or more supers on one hive, what would be the right bee-space between each two supers— $\frac{1}{4}$  or  $\frac{1}{2}$  inch?  
Bellaire, Mich., March 8. A. SCHOOLCRAFT.

[One-half inch would cause trouble. One-fourth inch is about right.—ED.]

# POULTRY DEPARTMENT

By A. I. ROOT.

## CHICKENS IN FLORIDA; THE "SIMPLICITY" INCUBATOR, ETC.

We left our Medina home on the evening of Nov. 15, and on the evening of the 17th were in our Florida "cottage in the woods," installed for the night. A week or two ago I asked my neighbor, Mr. Stanton, who had my fowls during the summer, to save up for me from my strain of Leghorns 12 or 14 dozen eggs for starting my incubator on arrival; and, accordingly, on the 19th I gave my new incubator 120 eggs, this being the first time I had ever made a trial of it with *all* the shelves filled. Mr. S. had 13 dozen eggs saved up for me; but he gave them to me with the following caution: There were only two males in my flock of 60 hens—my old \$5.00 one, and a cockerel; and, worst of all, he discovered, the day before my arrival, that the \$5.00 bird *could not be found*. He had missed several grown-up fowls before; and the only explanation for it was that a wildcat had jumped the four-foot netting fence, or that some one had *stolen* him.

Now, I always dislike to hear talk about "stealing" unless there is a very good reason for suspicion; and I have before remarked that my neighbor, Mr. Rood, has for years kept all his fowls roosting in an open shed, almost close up to the highway. Their perches are only about a yard high, and one could pick up a chicken any dark night, without even opening a door or gate to the hen-roost. Why, even the colored people in this region don't "steal chickens." I wonder if I shall offend (by "stepping on their toes") any of my good friends if I say right here that my good neighbor Ten Broeck (just over the poultry-fence) said yesterday, "Mr. Root, this street we live on is about a mile long, and fairly well settled; but there isn't a man or boy on the whole street who uses tobacco in any form or shape."

Now, isn't it a fair deduction that my rooster certainly wasn't stolen—at least not by any one in this neighborhood? No one knew exactly when he disappeared, but Mr. S. couldn't find him in the flock the day before I came. I decided to put the eggs in my incubators, however, for I wanted to make some experiments on fertility any way. You see I am working somewhat like our experiment stations. A farmer visited one of the branch stations near my Ohio home, and complained that the crops were not *nearly* as good as *he* could raise. The manager replied, "Of course not. The field or plot you are looking at has been planted to the same thing for *five years*, with no manure or fertilizing, to see the effect. Now look at this other plot on the same kind of ground."

Well, thanks to my new egg-tester, on the *third* day I had noticed that very few eggs

showed any fertility at all; and on the fifth day I found only *two dozen* out of the whole *156* eggs that had made a start. Now, lest some one might say it was partly my new incubator I put part of the eggs in my 70-egg Cypher. The result was just about the same. I suppose you all know that eggs tested out on the third or even fifth day are, to almost all intents and purposes, *fresh eggs*; but, of course, no one would sell them without explanation. Well, we had "eggs galore" three times a day for about a month. As Mrs. Root has some of her own notions about "incubator eggs," the heavy responsibility fell mostly on myself, and I have just been wondering if the "egg diet" may not explain, at least to some extent, why I have been so well and so happy (with my "chickens") for the past month.

On Thanksgiving day I started both incubators anew, giving the Cyphers 70 eggs just laid, and my own the 24, and enough more to make 120. With the Cyphers I followed directions to a dot, and got about a 70-per cent hatch on the 20th day. In fact, the chicks all came out in just a few hours. My own gave a very poor hatch, and some of them were not out until the 23d day. Please bear in mind, however, it had the 24 out of the lot of infertiles; and I have reason to believe that, when so many are infertile, the few fertile eggs are not likely to be of strong fertility.

Another thing in this connection: Where fowls are moved to new premises the eggs laid before they get to feel at home are not likely to be strongly fertile.

When I saw how things were going I procured in the neighborhood five good males for my 80 hens and pullets; but it was about ten days before I had a good per cent of strong fertility.

Again, on filling *all* the shelves of my incubator I found the lower shelf much colder than those above it. This I have now obviated by placing a disk of tin about four inches in diameter just above the flame of the lamp, preventing the heat from going so much up the chimney and making it first warm up the bottom of the water-boiler. (This takes more oil than I mentioned formerly.) Also, those openwork shelves gave too much ventilation and too strong a draft of air up through. I have remedied this by winding wide cotton tape so as to cover the spaces between the wooden slats. This gives a warmer atmosphere in each apartment, so that a lower temperature of the boiler keeps the eggs up to 103. The space under the boiler, around the lamp, I have also closed in with a sort of thick warm curtain to retain the heat better.

With the improved incubator oil I have spoken of, one can get along very well without a thermostat; but do not undertake to regulate the temperature by turning the flame of the lamp up or down. Do the regulating by the damper in the chimney. With this good oil you can get a very steady even flame for three or four days, or perhaps a week. The five-gallon sample of oil I got in Medina is rather better than the barrel I have

since purchased in Jacksonville, Fla. Get the blaze about where you have found it should be, and then make changes by opening and closing the damper at the top of the chimney.

Now, it may not transpire that my incubator is, at least as yet, a "great discovery;" but I have just got out something else that *is*. If you recall what I have written about fireless brooders you will remember that they cost (at least if you try to *buy* one) a good deal of money, and none of them are strictly fireless after all. I think I have cured at one stroke most of the two troubles mentioned above.

#### A. I. ROOT'S FIRELESS BROODER.

Get a cheap splint market basket, such as sell from five to ten cents. Get a thin board, 10 in. long and 3 or 4 wide, and tack it under one end of the basket for a doorstep. Just over the middle of this board cut a door for the chicks to go out and in. Now make two oblong hoops of stiff wire—one to drop inside and lie on the bottom of the basket, and the other enough larger so it will squeeze in near the top of the basket, and stay where you place it. Cover both hoops with burlap, and your brooder is ready for the chicks. The smaller hoop is mainly to keep the floor of the brooder clean. If you use galvanized wire you can wash and dry it quickly. By making bags of burlap, that the hoops will just slide into, you have a double thickness. For cold or cool weather the *sides* of the basket may be protected with flannel. Get  $\frac{3}{4}$  yard and fold it double so it will reach from the top rim of the basket down to the bottom, and a little more. Tack the upper edge to the top rim of the basket inside. I first put 28 chicks in such a basket, and they are doing splendidly. At first I put a folded cloth over the burlap covering at night; but they soon gave me to understand they were too warm, and needed more air. When just the thin open-work burlap was over them they were all right. Now, the low cost of this brooder is by no means its greatest advantage. You can pick it up with one finger and carry it indoors, when night comes, where it will also be safe from prowling enemies. After my brood of 28 did so well in the basket I tested a larger number, and last night had 62 chicks in just a common oblong ten-cent basket. Although the temperature was down to 42 in the woodshed, where I placed them, they got so warm I raised the bottom up on two bricks so as to let some cool air underneath. They came out in the morning, brisk and bright as crickets.

There is just one condition where a little artificial heat is needed, and I think this is true with all fireless brooders. When the strong healthy chicks are all outside on a cool day there is, of course, no heat of any kind in the brooder. If there are any weak or younger ones in the brood, a hot brick or a lamp brooder of some kind is almost a necessity. In my first experiment with 28 from the Cyphers incubator (and, of course, all hatched at once), I did not need any hot

bricks at all; but some from my machine, that came stringing along, would have perished without a hot brick in the basket afterward. When they all got into the basket at night, of course no brick was needed. Well, just now I feel like saying I want all eggs to go in the same day, and have all chicks come out the same day as far as possible; even if my machine will enable one (who wants to) to give his machine the eggs the day they are laid, and then have chicks hatching every day in the week. It can be done, but it doesn't pay unless you do it only for the fun of the thing. Have each flock of equal age and of equal strength as far as you can, and then what is suitable for one is suitable for all.

What about our "basket brooder" when it rains? Well, ours stand under a strip of enameled cloth tacked to the side of the house. One Sunday, when we were at church, a summer shower came up; and as the chicks were only about four days old they hardly knew enough to "go in when it rains," and when I found them they looked much like "drowned rats," as the expression goes, and were peeping piteously. I thought they would have to have artificial heat sure; but Mrs Root said if I put the whole 28 in their basket, as the weather was warm, she felt sure their collective animal heat would dry them out all right. I did so, and watched them anxiously for an hour. They seemed comfortable, but were at that time by no means dry. In about *two hours* they were cutting about in the sunshine outside about as fluffy and handsome as ever.

Of course the basket will answer only when they are small; and with fifty or more an extra basket will be needed so as to "divide the swarm," say when they are a month old or sooner. And, by the way, what is the objection to an empty barrel laid on its side? Two years ago I had seventy in a barrel, and they stayed there until they were old enough to fly up into the pine-trees. Unless the barrel is pretty good, a piece of oilcloth should be tacked on the upper side to keep the contents dry.

As nearly as I can make out, a bee-keeper, Mr. V. W. Clough, now of Aurora, Ills., first brought out a fireless brooder. Philo may be also an original inventor of it, and perhaps they both made their experiments public about the same time. I have just received one from Clough. It has a capacity of from half a dozen chicks to 200, and may be enlarged in size and also in height so as to keep half a dozen pullets until they are old enough to lay inside and hatch chickens. It is really a small Philo house, and can be used as such in his system. The price is \$5.00.

KEEPING CHICKENS IN FLORIDA; EXPENSE, ETC.

At present the grain for my 85 full-grown fowls costs about 20 cts. a day; and as we are getting 40 cts. a dozen for the eggs, six eggs pay the feed-bill. At present my 80 hens are giving about two dozen eggs per day. One friend in the North says I had

better stay all summer in Florida and try to make hens lay the year round before I extol this State much further. Well, my fowls have been here several summers, even if I have not; and my neighbor Stanton gave you a report or two in regard to eggs in summer. My neighbor Rood also keeps 50 or 75 the year round, and gets some eggs all the time. When I get time to "trap-nest" out my drones I will try to show you a better egg-yield than I am reporting now.

WHY DOES A SITTING HEN "SHAKE UP" HER EGGS WHEN SHE RETURNS TO HER NEST?

I should like to tell A. I. R. I was sorry he did not go on and say what that pullet he watched threw those straws for. I think it was to start all the little hearts to beating. Once when I had a cousin here on a visit she saw a young hen come off her nest, so we got the rake and hauled the eggs out from under the porch. She said, "I think they are good," and they did look like it; but I knew they could not be, so I asked her if she ever saw the inside of an egg when the heart just commenced to beat; and as she had not I said, "Your hands are warm, let me pour the contents of one out in them;" but, to my surprise, the chick was formed clear to the feet and wings. We watched the heart beat some 20 minutes, then we put the egg in the cat's dish, and in about half an hour she went back and it still beat. About ten minutes later she went again, and it had stopped; but a little shake started it, and it beat several minutes more. Now, had it been in the shell, and warmed, it would have kept on. My own theory is, that an old hen always settles herself on the nest so as to give the eggs that little shake. I have worked with incubators and sitting hens a long time to find out that one little point why the hen gets on her nest just so, especially when she comes in a hurry, and her eggs are cool. I read with interest your chicken talks as well as those for home and health.

R. KING.

In testing eggs with my new tester I have several times noticed the movement inside was very sluggish, or perhaps none at all, when the eggs had just been cooled. Warming them up seems to restore life; and it may be a little shake, as our brother suggests, wakens up the suspended animation. I once saw a doctor's patient, under the influence of chloroform, stop breathing. The old doctor gave him a little shake, and said, "Come! wake up and go on breathing." The patient, after a little pause, fetched a long breath, and was soon out of danger. Eggs at a *certain stage* can be kept three or four days—possibly a week, and be, of course, perfectly cold, and still revive and produce good chickens, if given to a hen to warm up, and, perhaps, also give them that "maternal shake" our friend calls our attention to.

GOOD FOR THE WYANDOTTES.

I have 13 pullets, hatched about April 1, White Wyandottes. The first one commenced to lay Oct. 1. By the 20th they were all laying. I did not keep a record of how many they laid in October; but in November they laid 289 eggs, or more than 22 each. Up to last night, Dec. 18, they laid 179 eggs, and are still at it.

Dalton, Pa., Dec. 17.

T. H. MILLER.

BURBANK, FLORIDA, THORNLESS CACTUS, ETC.

In the *Toronto Globe* for Nov. 6 there is an advertisement occupying a double page of a great newspaper, with pictures of Burbank's thornless cactus, and it really "takes the

cake" for extravagant advertising. We give you the opening sentences, which we find right under the immense picture of the spineless cactus.

WHAT THIS ANNOUNCEMENT MEANS TO YOU.

It means financial independence for the rest of your natural life.

It means that you secure a farm in Florida on which you can produce the Burbank and other products and ship them to the markets of the world, realizing the very highest prices.

It means that earnest men and women of the North, East, and West may free themselves from the shackles of wage-earning—or dispose of their non-productive acres—and in the glorious climate of Florida live a life of ease and comfort.

It means health—long life—freedom from worry—living under the turquoise skies of Florida engaged in the noblest of all callings, that of the producer who makes it possible for the rest of the world to exist.

It means that, in the years to come, when this great organization has fulfilled its allotted destiny, you will realize that you have not only made a tremendously profitable investment but that you have been instrumental in promoting the desires and ambitions of the world's greatest plant genius—Luther Burbank.

In the section of Florida wherein are located the Burbank-Ocala farms the soil is actually so rich that it could be used, if necessary, to fertilize other sections of the State.

Of course, we do not know how much Burbank had to do with it; but we do find a letter from him, in another place, as follows:

LUTHER BURBANK SAYS FLORIDA SOIL IS VERY RICH.

Santa Rosa, Cal., July 15, 1909.

Mr. H. C. Railey, President

New South Farm & Home Co., Chicago.

Dear Sir:—The samples of soil from Florida, which you have submitted for my inspection, are of very superior quality, so far as I can judge from samples. Of course, I do not know how truly the samples represent the general character of this soil; but if it is all like this, I would gladly pay one thousand dollars per acre for soil like it, for my own experiment grounds here. Just the right proportion of black leaf mold and fine sharp sand for the most perfect crops, especially of potatoes, melons, peas, beans, celery, and other garden crops; also for berries or farm crops. My new smooth rapid-growing cactus should do wonderfully well in such soil.

Yours very truly, LUTHER BURBANK.

You can find all over the State of Florida deserted plantations where somebody "blew in" his money, and afterward felt so disgusted with the outcome (or income, rather) that he left every thing to go to waste and ruin. Once more let me say, before you invest a copper in Florida real estate, go down and take a look and see what you are buying before you hand over the money.

THE "OCALA BURBANK TRACT" OF FLORIDA LAND, ETC.

Below is a sample of the letters I am getting from almost all over the North:

I am sending you a post card. I am thinking of investing in ten acres of this "Ocala Burbank Tract." Will you please write a few words on the enclosed card and tell me what you know about this tract of land. If you think this land is as good as where you are I will send the company \$10.00 to secure ten acres of it. If you think this is good land for celery, lettuce, etc., as it is where you are, I will come down there next month and take a look at it.

Merino, Colo., Nov. 25.

T. J. LANDRUM.

My impression is that Burbank has nothing to do with this speculation, and perhaps he has never given these people the right to use his name and his letters as they are using them. This is true, however: He has, at

least so far as I know, made no protest against it. Let me say to friend Landrum and others, there are at least two great obstacles in the way of the Ocala tract being as good as Manatee Co. for celery, lettuce, etc. Frosts are very much worse in the north and there are no artesian wells in that region.

A "KNOCK" IS A "HOLD-UP."

Last spring one of our readers became interested in the St. John's Development Company, which operated in Florida lands. After an investigation we became convinced that the land was such that it would not make a good investment. We wrote our friend to this effect, and he seems to have turned the letter over to the operating company. It was effective at least. The following is an extract from the letter he received in reply:

We are in receipt of your favor with the letter from the *Rural New-Yorker* attached, and we note what they say in regard to our lands in Florida. We did guarantee to return money to customers who were not satisfied after making an investigation; but we believe that, in fairness to all, an investigation would be a little fairer than writing to a personal friend in New York State, who has not seen the land, probably has never been in Florida, and who runs a cheap magazine that is practically unknown. If we had been using the columns of this magazine, they, no doubt, would have said glowing things about our property, and we consider this "knock" nothing more than a hold-up. We shall be only too glad to refund money to any one who is willing to take the word of any one so little known, and who has no right to speak authoritatively on this subject.

It is too bad about this "cheap magazine" which is "so little known." The writer owns a piece of land in Florida directly across the lake from "St. John's Park." All along the shore are deserted houses and ruins of orange-groves. In former years these houses were occupied; but death lurked in the damp climate, and northern people could not live there. We have reports from people who have known the land in question for years. They had chances to buy it, but would not touch it.—*Rural New-Yorker*, Dec. 11.

#### THE WONDERBERRY UP TO DATE.

We clip the following from the *Rural New-Yorker* of Dec. 11:

*What has been the result of your campaign against the wonderberry?* J. S. A.

We can answer that better when Mr. John Lewis Childs issues his next catalog. Some of the other catalogs will also help answer the question. We understand that Mr. Childs has a very large stock of wonderberry seed on hand. It was also reported at one time that he intended spending \$20,000 in advertising it. We have proved beyond any question that the seeds which Mr. Childs sold developed into plants of the black nightshade. Luther Burbank offered \$10,000 if we or any one else could prove that the wonderberry was a black nightshade, and we have offered him proof from hundreds of sources. Among others who testify are the experts of the United States Department of Agriculture; dozens of botanists at the State experiment stations; Dr. C. H. Peck, New York State Botanist; Dr. L. H. Pammel, of Iowa; the botanists of the Kew Gardens, London, England; the Harvard Botanical Garden; the Royal Horticultural Society of England, and the Royal Horticultural Society of France. In addition to this, plants identical in character with the wonderberry have been found growing in Mexico and Texas, where they have been known for years. All this has been put up to Mr. Burbank, and he can have more if he wants. Thus far not a dollar of that \$10,000 has been separated, and not a word of apology to the American people for letting loose his "wonderberry" as a new "creation." The effect of this childish folly upon Mr. Burbank and his later "creations" remains to be seen.

#### "BELIEVEST THOU THIS?"

Mr. A. I. Root.—I am sending you two clippings from the *Farm News*, which I thought might interest you. By the way, the *News* is published in Dallas, Texas. Your Home papers become more and more interesting, and you ask me, "Believest thou this?" Yes, I believe; and your earnest words have strengthened this belief. If I thought you were not too busy I could write much to you. Suffice it to say, that in this home your papers are eagerly read, and are working miracles; and every one refers to you as "Father Root."

MADELEIENE E. FRUITT.

Ranch Vigo, Vancourt, Texas, Sept. 3.

## TEMPERANCE.

"NO DRUNKARDS NOR CIGARETTE FIENDS ON THE PAYROLL."

We copy the following from the front page of the *American Issue* for November:

FROM THE GOVERNOR OF KANSAS.

It is a common thing in Kansas, in a majority of counties, not to have a prisoner in jail, and most of those fellows gathered in jails are there because of intoxicating liquors. There is a close relation between drunkenness and jails and penitentiaries. It means a great saving to the people of this State and nation in an economic way. I expect, while I am governor of Kansas, to stand for the best things in public and private life. We won't have any drunkards on the State payroll while I am governor, and we won't have any cigarette fiends on our payroll either. I am going to have this State government stand up for every thing that is good and noble, and for high ideals, and boost Kansas just as high as we can.

GOVERNOR STUBBS, of Kansas.

May God be praised for a governor who can honestly utter such sentiments. Now have we any more governors who have the willingness and courage to stand by the side of Gov. Stubbs?

#### SALOONS LOSING GRIP BEFORE DRY CRUSADE.

"Eleven thousand saloons voted out of existence, and 4000 more forced to close in 1908."

This is the record of the things accomplished by the Anti-saloon League of America, according to Dr. P. A. Baker, general superintendent of the league, in his biennial address before the semi-annual convention in session at Orchestra Hall last night.

"Since January 1, 1909," he said, "saloons have been closed at the rate of forty a day; but that 70 per cent of the area of the United States forbids licensed liquor traffic tells only a part of the visible results. No power of evil on earth can long withstand this continued onslaught. The gates of hell can not prevail against it."

"There is no class that suffers so much from the drink traffic as do those who perform manual labor, and there is no class so much exploited by the saloon and brewery element as they. The great labor movement is yet to become a great spiritual and religious movement. Organized labor is fundamentally a holy crusade. It often blunders, but it is a struggle toward light and justice and a square deal. It is striving for a principle of righteousness, but all the while, as a body, refusing to give due recognition to the source of all righteousness. Soon they will turn to the carpenter's Son and his church for assistance."

"We must not for a moment forget that this liquor problem is the church's problem, that the church must solve it. It can not turn it over to the Woman's Christian Temperance Union. It can not turn it over to any political party. It is not the province of a political party to inaugurate moral issues."

Dr. Baker also paid a tribute to the work of the W. C. T. U. in doing educational work in the schools, as did other speakers during during the day.

Speaker Cannon came in for considerable severe censure at the morning and afternoon sessions at Handel Hall, and a concerted war against the congressional leader was promised. He was blamed for the defeat of efforts to secure anti-liquor legislation.

"We make no charges," said Legislative Superintendent William H. Anderson, in making his report, "but point to the unerring accuracy with which circumstances just simply "happened" to prevent putting any real burden on the liquor interests in the recent tariff law."—*Chicago Record*.

The Department of Agriculture of the State of New York will hold bee-keepers' institutes at the following places and dates: Amsterdam, Feb. 8; Syracuse, Feb. 9; Watertown, Feb. 10; Rochester, Feb. 11. There will be three sessions daily. All of the New York State inspectors are expected to be present, and will be assisted by local talent. Every one interested in apiculture is invited to attend and take part in the discussions. A special invitation is extended to the ladies.

W. D. WRIGHT, Agent.

# GLEANINGS IN BEE CULTURE

## EDITORIAL

By E. R. ROOT.

DID it ever occur to you that a breakfast food tastes better, when honey is used to sweeten it, when it is cold than when hot? Honey poured over any hot food will lose a part of its delicate flavor, consequently the editor has his breakfast food served at the same time with the rest of the family, but eats it last of all, making it a sort of dessert. By that time it has cooled; then he spreads upon it mountain sage or alfalfa honey with a liberal supply of good cream. None of the flavor of the honey is lost, and the breakfast food itself is just as good—yes, even better. Try it, dear reader, and see if you do not agree with us.

NEWSPAPERS and magazines all over the country are discussing the present high cost of living. What is the reason for the oftentimes excessive cost of food? Has honey increased in price proportionately? These and other questions relative to the topic will be dealt with in our next issue by two of our correspondents who are in a position to speak with authority.

The following letter from O. L. Hershiser is timely and to the point:

It seems to me there is something wrong somewhere when the price of living is getting out of sight and the prices of apiarian products remain stationary. I want to see better prices for honey if every thing else is to be high, so we bee-keepers may have a fair show in the fight for a livelihood. I am of the opinion that a lot of bee-keepers are to blame. Many others do not read bee journals or market quotations, and sell in ignorance of the value of their product. If honey were even a cent higher it would do a lot of good. It is impossible to make any thing putting up honey in tumblers when it is sold by jobbers here at 85 cts. per doz.

### THE COVER DESIGN; BEE-KEEPERS OF ANCIENT GREECE.

WE do not know when the Greeks became bee-keepers; yet at a period of time when many other great nations were yet unborn we find these classic people engaged in honey production. They seem to have produced vast quantities of this delicious food, for the poets and historians are very profuse in their praises of the industry. This alone is proof that the bee-keeper was a factor worthy of attention. The fame of the honey of Mt. Hymettus reached from the Pillars of Hercules to Colchis.

The drawing shows a Greek bee-keeper of the "Macedonian Supremacy" period paying a forced tribute of honey to the tax collector. The hives shown are not of straw, as they appear to be, but are made of woven splints of wood, much after the fashion of the hickory corn-baskets of our fathers. The bees of Greece were quite likely of the yellow variety.

### THE ALEXANDER METHOD OF CURING FOUL BROOD (BLACK BROOD).

MORE evidence is still coming in, showing that there is undoubtedly some merit, at least, in the Alexander cure. One letter, especially, comes from the author of the McEvoy treatment, and we are glad to place this before our readers:

*Mr. E. R. Root:*—Dr. C. C. Miller did well in curing his apiary of disease in an off year and in a very trying time. He has few equals as a practical bee-keeper. I am much pleased over his success, as it confirms almost all I have ever claimed. I felt like going over the doctor's article and writing a few lines which would be in his favor; but as others will, no doubt, take a hand, I will leave it to them.

We are having a fine winter so far—ground all covered with snow enough to save clover if it remains long enough.

WM. MCEVOY.

Woodburn, Ontario, Can.

Italics ours. As this letter came unsolicited, and from one of the best authorities on brood diseases in the world, it doubtless will have some weight. We are anxious to gather in all the testimony both for and against the Alexander treatment, and we hope to hear from others, including, of course, Mr. McEvoy.

### THE CENSUS OF AGRICULTURE TO BE TAKEN THIS YEAR; THE UNRELIABILITY OF FORMER CENSUS FIGURES AS THEY RELATE TO BEE CULTURE; SOME DIFFICULTIES FOR 1909.

ACCORDING to the usual practice of a decennial census, the thirteenth census of the United States will be made this year. The agricultural census, which will form part of this general census, will be taken between April 15 and May 1, and the enumeration will be as of April 15. The reports on crops will be for the year 1909. The bee-keepers of the country will be interested in this census, for this is almost the only means which we have at present of learning the extent of the industry or what its growth has been.

We can supplement census data somewhat by general impressions and careful estimates; but, unfortunately, census figures in the past have not been very satisfactory. For example, the census of 1900 gave the total hon-

ey production for 1899 as 61,196,160 pounds—a figure so low that the annual comb-honey crop alone would probably exceed it. Unfortunately, only those apiaries on farms were included in the enumeration, and it is, of course, obvious that a very large percentage of apiaries, especially in the East, are not on farms but on smaller tracts of land in towns and cities. A farm in the census is defined as at least four acres, or enough to support the owner. It is to be hoped that bee-keeping will be included in the enumeration in towns and cities in the next census.

It is most unfortunate that the honey crop of 1909 has been a complete failure in so many localities. This will make the recorded figures of little value as representing the industry as it normally exists, or as indicating the value of the honey-bee as a producer. The enumeration of the number of colonies on April 15 will give the least number possible for the winter losses, which are heavy when we consider all classes of bee-keepers, will have been completed, and there will by that time have been no increase for 1910 except in the South. It will be obviously unfair to estimate the average production per colony by comparing the crop of 1909 with the spring count of 1910 except in a very general way.

Bee-keepers should make it a point to see to it that their bees are included when the enumerators visit them so that we can make as good a showing as possible. It may also be well for us in giving the crop for 1909 to designate honey-dew honey separately so as to attract the attention of the census authorities to the abnormalities of the year 1909.

#### SOME INTERESTING WINTER READING.

A YEAR ago we published a portion of a contribution on the natural history of the honey-bee, by Dr. H. von Buttel-Reepen. This was entitled, "Are Bees Reflex Machines?" but the very nature of the title was such as to cause our readers to believe that it was an abstruse scientific work beyond their comprehension. As a natural consequence, these papers did not at the time attract any considerable attention. Dr. von Buttel-Reepen, while a scientific man, is also a practical bee-keeper. He conducted a series of experiments that are not only exceedingly interesting but valuable from a practical standpoint. During the long winter evenings it is our opinion that many of our practical honey-producers will find this to be exceedingly profitable reading-matter. Here is a list of the titles and subheads:

#### THE HIVE ODOR AND ITS REACTIONS.

- Modification of Reactions toward the Hive Odor.
- The Swarming-out of a Queenless Colony.
- Intensifying the Reaction.
- Overcoming the Reactions toward Hive Odor.
- The Odor of the Queen.
- The Brood Odor.
- The Indifferent Odor of Young Bees.
- Failure of the Hive-odor Reactions in Queens and Drones.
- Abnormal Hive Odor.

#### THE MEANS OF COMMUNICATION IN BEES.

- Investigations with Colonies from which the Queens are Taken.

- Behavior of a Queenless Swarm.
- Disregard of a Queen in Open Air.
- Hearing Capacity and Sensations of Sound Present.
- Experiments on Swarms.
- The Infecting Influence of the Swarm-tone.
- The Enticing Note of Bees.
- The Teeting and Quahking of a Queen.
- The Queen's Tone of Fear.
- MEMORY OF PLACE IN BEES.
- The Paths of Bees and their Direction.
- Disappearance of the Memory for Location through Narcotization.
- The Box Experiment.
- The Loss of Memory for Location through Swarm Dizziness.
- Associations of Impressions.
- Memory for the Feeding-place in the Hive.
- Conduct of Bees in the Buckwheat Season.
- Are Bees Attracted by the Color of Flowers or by the Nectar?
- Place Perception in the Queen.
- Memory for Locality in Scouting Bees.
- The Eyes of Bees.
- The Flight of Orientation.
- The Finding of the Hive through the Senses of Sight and Smell.
- Bethe's Tree Experiment.
- Special Capacity for Orientation in Bees.
- The Influence of Weather Conditions on the Sense of Sight, therefore on the Ability to Orient.
- Influence of Color on Bees.
- FURTHER CONTRIBUTIONS TO THE NATURAL HISTORY.
- The Flight of Bees into a Room.
- The Behavior of Robbing Bees.
- The Origin of Hostile Conduct.
- The Vanishing of Instincts with the Decrease in the Strength of a Colony.
- Reactions toward Flight.
- The Formation of the Honey-comb.
- The Play Instinct in Bees.
- Bibliography.

The work was originally written in German, but was recently revised and afterward translated into English by one who has not only a knowledge of bees but of scientific terms. While this work really cost us more than any other of equal size, we are going to offer it to our readers on conditions that will place it within easy reach. It has 50 pages the size of this; and to any one of our subscribers who will send us \$1.00 before his subscription expires, or, if the subscription has expired, will pay up all back arrearages and \$1.00 for one year in advance, we will send a copy of this work postpaid. The general current of the discussion that will be running during the year 1910 in these pages will make this contribution exceedingly helpful.

#### ECHOES FROM THE LAST CONVENTION OF THE NATIONAL BEE-KEEPERS' ASSOCIATION AT SIOUX CITY.

THE last Annual Report of the National Association, giving a financial statement, complete list of the membership, and report of the proceedings, has been issued. Among other things discussed was the question of fastening foundation in brood-frames and the various methods of staying it by means of wire or splints. In this connection Mr. O. O. Poppleton drew attention to a method that he had been using with considerable success, that employed neither wire nor splints. Mr. Poppleton said:

Some six or eight years ago a gentleman in California sent me a permit to use his patent, and it is the finest I have ever used; but on account of its being patented I have never given it out very much. Mr. Hill, the late editor of the *American Bee-keeper*, in Florida,

and myself tried to retain the patent for the purpose of giving it to the bee-keeping world, but we could not succeed, and we dropped the thing. We use it ourselves. It beats wiring. I have not used wire for years. It is a very simple thing indeed. I have now in use something very similar to the old Given press. I had one in the apiary when I went to Cuba, and in using that I would make a double dip of the top of each sheet—that is, dip sidewise instead of endwise, and by doing it that way and pressing it I got sheets that would not stretch, having the upper half very heavy and the lower half very thin. I tried to interest the Roots, but they said there was some mechanical difficulty in running foundation by that method. Then I tried again a few years ago to interest them, but they were then working on another scheme, and did not take it up. This process is simply forcing the wax to any part of the section that you want it by brushing melted wax over the surface. It also adds wax to the edges of the cells, and in some way or other strengthens them. I think that also solves the question of feeding wax to the bees for them to use. I take my comb, and I have a little dish over a small kerosene-stove so as to keep the wax melted. I use an ordinary three-inch flat varnish-brush. I take up all the wax I can, and just rub it over the upper half until that wax will press out over the edges of the cells. It adds wax to the cells in the upper part, and I have no trouble. I use a quarter-inch-deep foundation. I have the finest combs I have ever had in my life. It solves the entire problem of stretching combs. The gentleman who has patented this process lives in Southern California, and his name is Henry Vogeler. It was patented in 1900. I would no more think of going back to wires or doing without it than I would of trying to keep bees that would not rob.

A patent was issued to Mr. Henry Vogeler, New Castle, Pa., April 17, 1900. The specific claim covering the process reads as follows:

"As an improved article of manufacture, the artificial comb foundation having its cells constructed with thick beads extending around and constituting their rims or edges, as and for the purpose specified."

Any person who desires to use this process should make arrangements with Mr. Vogeler.

#### RENDERING COMBS INTO WAX.

On this subject Mr. C. P. Dadant, who, as everybody knows, is an authority on the subject, had this to say:

Beeswax can be overheated with water by overboiling. The water, in boiling through the beeswax, will beat it into a grainy substance which looks like pulp. You can change your cakes into powder from one end to the other by overboiling—by allowing the water to beat your wax into a grainy mass. If you have seen something like corn meal at the bottom of your cakes it is beeswax; and the only way in which you can return that is by dry melting. There are several things about the rendering of combs that are of some importance to know. Do not melt your beeswax with water in pans that contain any iron. Iron will turn your wax black. There are several little points that should be considered. Do not use any acids in rendering wax. Most people, when they do use acid, use twenty times as much as they need. It takes the smell of the bees out of the beeswax. Our friend Mr. Kretschmer said, "Soak your combs a long time." That is right. Take the old cocoons and crush them as much as you can, so that they will not take in the beeswax. Those cocoons have the shape of a honey-cell, and they remain there after they are crushed, and there is no chance for the beeswax to get into them. Put your combs in clean water and melt them. It is not necessary to use a press until you have taken the best of your wax out. We never do use a press with cappings, but we use a press for the residue. A gentleman asked me a question. The boiling must be with water; and if you spoil the beeswax and get it grainy, that part which is grainy, and which is more or less dirty, and which contains a good deal of water, must be returned to good shape by dry heat. Then you will not have as good beeswax as you would otherwise have. I have had shipments of beeswax that were so badly beaten with water that they would lose one-fifth. It would not look very much like beeswax. It would look like a cake made of ground corn. I had a long discussion in regard to pollen in beeswax. I did not know at first that there was any such thing; but I found it out when we were making foundation.

We were throwing away our residue containing that grainy substance. In the course of time it melted in the sun, and after a while we took up this residue and got 100 lbs. of beeswax from it.

#### USING HONEY AGAIN FROM FOUL-BROODY HIVES, EVEN AFTER IT HAS BEEN BOILED.

On this subject Mr. N. E. France, General Manager of the National Bee-keepers' Association, and official foul-brood inspector for Wisconsin, has some decided ideas.

Mr. President, the care of honey from infected hives has been one of the greatest hobbies of my work in our State. About five or six weeks ago I received notice that a whole apiary was to be moved from Wisconsin to Iowa, and that there was infection in that yard. I was not aware of it. I went there and found infection; and in order to hold the man I put a printed quarantine card upon the yard, and said, "You dare not move one thing. It must be treated right here." But he said, "I am away from home on expense, and I can not afford to stay." I replied, "Sir, if you were sick with the smallpox you would stay. This is not smallpox, but to the bees it is equal to it."

He had four colonies of bees all ready for shipment, but they never left the city. The honey was extracted from those combs with the understanding that it should all be used as a food consumption in two families who knew what they were using, and that the dishes or cans in which it came were at my mercy, and they were disposed of. Infected honey, I have not been able to say positively, is injurious to human health, but I can not for one moment recommend it. I have used some of that honey purposely from some badly infected combs myself, and I fancy I have received some ill effects temporarily. One man in one county extracted honey where the brown rosy matter was in some combs, and went into the honey visible to the naked eye, and that honey he himself used, and his family, and he is still living and in good health. To go back to the point of what we were going to allow with regard to this honey, in two cases where they had considerable of it I allowed them to ship it to bakers, marking the barrels and notifying them that it was infected honey, and that those barrels must be burned. Otherwise I have not allowed any one, where I have known of infected honey in the State, to do any thing with that honey but either to destroy it totally or boil it, after which it is not of any value; because if you boil it enough you have blackened your honey till there is no commercial value in it.

Mr. Ramer.—Would it do to feed to the bees again after boiling?

Mr. France.—Don't take the chance. I believe it is possible that that honey can be boiled and used again, from the fact that I made a desperate effort twelve years ago to save every thing in a yard of over 200 infected colonies. We took the hives, cleaned them, and put the bees back into the same hives, extracted and boiled the honey, and, having a foundation outfit on the farm, we made some infected wax into comb foundation, put the bees on to that, and fed them with boiled infected honey. That was twelve years ago, and no disease has shown up since; but I would not want that to become a general public statement, from the fact that any one else might not be as thorough. We boiled that honey to a finish. I have seen honey that has been called boiled in which the germs of the disease were plentiful and alive. There have been in my State and in adjoining ones, not giving names, nine instances where honey from an unknown source has been used as a means of feeding bees for winter stores, and in those cases it has brought the disease to their yards. Do not for one moment buy honey to feed to your bees unless you know positively the source it comes from. Sugar syrup is better than to take those chances.

Dr. Bohrer.—I have some at home canned up, but I will not sell it. I am too good a Christian to sell it. I would as soon go into my neighbor's barn and steal his horses. As to extracting it, when it reaches the stage Mr. France has spoken of, that is, with a large number of diseased larvae, and decomposed and rosy. I never extracted any honey from a frame of that kind. I simply take the frames that have no brood in them and extract the honey from them. If I use that at all, I use it on my own table in the winter time. Where Mr. Poppleton lives he had better not use it at all, because he lives in a warmer climate and bees get out every day in the year, and they may get at that honey. You must not take any chances. If you can not use it during the cold winter weather it is better to dig a hole and bury it.

## STRAY STRAWS

BY DR. C. C. MILLER, MARENGO, ILL.

THAT 15-INCH snow-blanket has had another 15 inches added in this locality.

LIGHT-BROOD foundation with 7 splints works all right here.

"WE DO NOT BELIEVE cold actually kills bees," p. 35. No, no more than it does people. But it may kill either bees or people.

IN THE *Canadian Bee Journal*, page 424, J. E. Hand reports successful wintering on solid slabs of honey with two inches between the combs.

H. E. CROWTHER had no buckling with 5-inch splints, and I had. He gives the reason, p. 22. He used horizontal wires and I used none.

LOUIS SCHOLL, you're a goose. There you go, p. 39, trying to get those Colorado fellows to run for bulk honey; and then when they flood your market with it where will you be?

TO EXCLUDE the queen from upper stories, J. C. Clayton, in the first story over the brood-chamber, spaces extracting-combs two inches. He says the queen will not pass up through this.—*British B. J.*, 474.

A PLANT-LOUSE, in five hours, secretes an amount of honey-dew equal to the bulk of its own body. A linden-tree with 24,000 leaves can furnish 50 pounds of honey-dew.—*Deutsche Imker aus Boehmen*, 406.

I THINK it has been suggested that bees cluster front with honey further back because the honey is thus safer from robbers. Is it not just possible, also, that the brood-nest is near the entrance for the sake of the fresher air there. [That has always been our theory.—ED.]

C. G. HULICK, p. 43, if moisture here would use up an unpainted hive in two years, as it does yours, I think I'd paint. But when it lasts 25 years, I'd rather have the advantages of no paint. The chief one is that the moisture from the bees' breath dries out more quickly in an unpainted hive.

I HAVE A NOTION (but I don't know) that solid frames of honey with a two-inch space beneath will be all right for outdoor wintering. But the bees will at once proceed to make your sort of brood-nest, Mr. Editor. [They may make that nest, but the cold slabs of honey in the mean time may give them a set back.—ED.]

G. M. DOOLITTLE, I always supposed that, in all normal superseding, queen-cells were started before the death of the queen; and until your statement, p. 759, I never knew that blacks used post-constructed cells for superseding—never saw it in print before. But I can't understand why a queen from a larva a day or two old isn't just as good as one from an egg laid in a queen-cell.

D. M. MACDONALD, *British B. J.*, 469, quoting American approval of sweet clover, says: "I have frequently intended asking if any

one in this country grows sweet clover. . . . I wish I had some seed!" Is it possible that there is a spot in Scotland where the plant is not known, either under the name melilot, Bokhara, or sweet clover? If so, my Scotch brother, let me know, and I'll send you some seed.

GERMAN bee journals are talking about the discovery of Dr. Kuestenmacher that honey contains more albumen than has heretofore been credited to it, in a form more readily assimilable than in any other albuminous food, making it specially valuable from a medicinal standpoint, and making it thus possible to distinguish chemically between pure and adulterated honey.

THE GERMAN EMPIRE, according to the census of Dec. 2, 1907, now made public, averages 19.2 colonies of bees to the square mile, ranging from 9.58 to 44. *Deutsche Bienen-zucht*, 184, in giving these figures, says the difference is not so much due to difference in pasturage as to the advancement of bee culture in the different parts. If we plant the apiaries three miles apart there will be from 86 to 396 colonies in each apiary, averaging 172. As pasturage is supposed to be better here than in Germany, it looks as if E. W. Alexander was right as to our being too easily scared about overstocking. Or does their overstocking account for their poorer yields?

C. F. BENDER says, p. 43, "But I think it is perfectly safe to keep them in pairs, as I never knew bees to mistake right and left." I'm afraid the importance of that statement is not generally understood as it should be; and Mr. Bender gives a striking proof of its correctness. Suppose you have a straight row of hives 8 feet apart in the row. Now replace each single hive with a pair, and there will be no more mistakes about entering wrong hives than when the hives stood single. The bees of No. 7 may make the mistake of entering No. 5 or No. 9, but they will never enter No. 8, the other hive of the pair. You see that, by putting hives in pairs, you double the number on the same ground without at all increasing the danger of entering wrong hives.

THE TWO WAYS I treated black brood are run together as one, p. 45, and the mistake is made of giving combs instead of empty frames. The pith of the shaking treatment is this: Brush, and leave in the hive one foul comb and two empty frames (no starters); when comb and eggs appear in empty frames, remove foul comb and fill up with foundation. The improved Alexander treatment runs thus: Unqueen; ten days later destroy cells and give a virgin. That's all. But please remember this is not for American foul brood. [It remains to be seen whether colonies given this treatment will stay cured next year, and the year after that. There are some who say European foul brood (black brood) can be cured this way for one season, but that it may come back the year following. Keep a sharp eye on these colonies next season and report.—ED.]

## BEE-KEEPING AMONG THE ROCKIES.

BY WESLEY FOSTER, BOULDER, COL.

### SAGGING OF SECTION-HOLDERS.

When a super gets full of honey the section-holders sag in the middle and destroy the correct bee-space above and below, and also throw some of the sections out of shape. A section-holder slat should be  $\frac{3}{8}$  in. instead of  $\frac{1}{4}$  to overcome this fault. I have seen the holders sagging nearly the full bee-space, and resting on the tops of the frames.

### A HARD WINTER.

On Thanksgiving day the weather changed from the usual Colorado fall, of perfect days, to regular severe cold of the Eastern State variety, with no warm weather up to this time, except for a few days about Christmas, when the bees had a cleansing flight. Few stores have been consumed, and the dead bees have not shown up much on the bottom-boards. On the whole I think outdoor-wintered bees are doing just as well as the most hopeful could expect. The prolonged cold may tell on the vitality of the colonies later on, but we are not grieving yet. Hot cakes and biscuits are being eaten these cold snappy days, and I can see where last year's crop is fast passing to the "ultimate consumer." The glucose people seem to profit also by the hot-cake weather, and no wonder; for a gallon of corn syrup costs but fifty cents, while honey is a dollar and a half. Many do not object to poor food if they can get it cheaper. What we bee-keepers must do is to educate the public to use the best and purest foods.

Comb honey still unsold which has commenced to granulate is the most serious difficulty to be met in the rapid spread of honey consumption; so all cases should be gone over, and the slightly candied combs removed. This can be melted down, or sold to those who like the candied article.

### THE RANGE OF FLIGHT VARIES.

This question of the distance bees fly for honey depends much on differing conditions, topography of the range, direction the prevailing wind blows, fragrance and abundance of the honey flora, position and facing of the bee-yard. All these factors enter in quite largely before one can say when a location is worth any thing or is already overstocked.

First, taking up the topography of the district over which the bees have to forage. An apiary which we bought was located in a sort of hole. Dry hills rose on each side; and, though the distance to a good number of alfalfa fields was not far, those bees did only about half as well as some which were only three-quarters of a mile distant. I can come to no conclusion but that those bees could not see, smell, or hear of the blossoming fields till too late to do really good work. The odds were too much for the bees to com-

bat in some particulars. Whether I have offered the real solution I can not say; but the fact remains that bees but a short distance away gathered a good surplus.

As to the wind affecting the direction bees fly, I think this would apply only where the wind is very constant, making it almost impossible for flight in other directions. One would think bees could see that, if they fly against the wind, the wind will be at their backs on the home stretch; but if the wind continually blows them back, making access to the desirable fields difficult, they are not likely to persist against the odds.

One reason the sweet clover is visited by the bees so plentifully is that it is so much more pronounced in odor than alfalfa. I would not admit that sweet clover is more fragrant, but it has more odor.

As to bees guiding their flight according to the way they get started from the apiary, I think this depends very largely on the abundance of nectar in the flowers straight ahead. If a long dense grove of trees cuts off sight and flight to the west while there is an abundance of virgin territory to the east it is reasonable to suppose that very little work will be done through that grove barrier till the district to the east begins to fail.

### THE ANSWER TO CROWTHER'S PROBLEM; THE DISTANCE OF A GOOD WATER SUPPLY.

Giving my ideas on Mr. Crowther's problem, page 22, Jan. 1, I will say that I think the bees located three-quarters of a mile above the irrigation canal were so far removed from the good honey acreage that much energy was wasted in gathering a surplus. Bees do not fly at all profitably for honey more than a mile and a half, and that three-fourths mile of barren ground discouraged the more timid bees, if there were such, and I do not see why we can not say this, for some bees are out in the morning as soon as the sun rises, while the large majority do not start to work till encouraged by the successful efforts of the early ones.

The distance from a good water supply would account for some of this difference in yield. I do not imagine that a great barren plain looks very inviting to the bees, for it is their nature to live among trees and grass and flowers. I wonder how many of the readers know the lost and lonesome feeling that comes from being alone on a level stretch of buffalo grass and sand. The only thing bearable is knowing the distance to water, grass, and civilization. But suppose one were a bee, and did not know whether there was any thing green on earth; then he would feel like curling up in a ball and giving up this world as a great mistake. I imagine that bees placed out a mile from any irrigated and feel like doing this very thing.

Whether bees will fly seven miles down from the mountains to the valley and gather alfalfa honey, I must say that I think the territory nearer home should be scrutinized very carefully before placing a great deal of confidence in the seven-mile flight.

## NOTES FROM CANADA

BY R. F. HOLTERMANN.

### FOUL-BROOD ILLUSTRATED.

The Department of Agriculture for Ontario has ordered from Germany 5000 copies of a lithograph of a foul-broody comb which was published by the *Leipziger Bienen Zeitung* some time ago. It is an excellent illustration, and it will be a great educator as to the appearance of foul brood in the comb.

### POISONOUS COMB HONEY.

On page 21, Jan. 1, Geo. M. Lord relates an experience in connection with some comb honey taken from the eaves of a neighbor's house, which gave cramps and nausea. I have heard of honey taken from a bee-tree having this effect when bees had been crushed between the comb, causing them to sting the comb and inject poison into the honey.

### THE TIME WHEN BASSWOOD BLOSSOMS.

G. M. Doolittle, page 1910, draws attention to the great variation in the time of blossoming of basswoods. Some always blossom early, while others are always late. I have frequently noticed this. I am, however, also of the opinion that two localities 100 miles apart may make a difference of ten to twelve days in the time of blossoming. I have such a case in mind now.

### THE MUSIC OF BEES.

When I read on page 29, Jan. 1, the statement of P. W. Richards, to the effect that he, having a musical training, can tell by the pitch of the note the bees make whether the queen is there, and if so in what part of the hive, I felt like placing the following notice in GLEANINGS:

"Wanted, an expert musician who also wants to learn bee-keeping, we to exchange knowledge."

But I do believe this is possible, and I believe F. J. Miller, London, Ont., deserves great credit for being courageous enough to bring forward so new a thought.

### THE FOLLY OF MIXED GRADING.

On page 555 Editor Root endorses the statement made by J. E. Crane, page 560. Both condemn making up a shipment where No. 1 and No. 2 are mixed, or the dark honey is with light. There has been altogether too much of this done. If the purchaser has been foolish enough to pay for the goods in advance, and the seller is irresponsible financially, the purchaser is very cautious about purchasing any comb honey in future. If the seller has not been paid for his goods in advance he will want to deduct enough from the original price to cover all trouble, risk, and loss; and if he is as unscrupulous as the seller he will try to deduct a good deal more. There are good bee-keepers who can not find the highest market for their honey; but too many when they have a customer do not hold him, because the sample they sent

is better than the goods produced, or the goods shipped are not equal to the description by word of mouth or letter.

J. L. BYER.

The readers will be pleased to have seen the Byer family group as shown on p. 779, Dec. 15. Mr. Byer comes of bee-keeping stock; the family is well and favorably known through a wide section of country, and it has been my pleasure to visit among them several times. Our friend is not only a good writer but a good speaker. When he speaks he does so with energy; and he, Sibbald, Miller, and several others would make excellent farmers'-institute speakers, which, in my estimation, are much needed in Ontario if the slipshod and disinterested bee-keeper, who will not go to a bee-convention or take a bee-paper, is to be reached.

### ROBBER-TRAPS.

Referring again to robber-traps, I can not see how honest bees, that are active in their instincts, and ready to avail themselves of every opportunity to gather honey, can help being drawn into these traps. If there is any law in the life of the bee that discriminates between the honey which it is legitimate for her to gather and that which is not, I don't know of it. If I were buying bees I would give the preference, other things being equal, to the colony which would be the quickest to scent or find out the best source of honey, no matter what that source might be; and I doubt if there would be any distinction manifested as to quickness of discernment in stocks where the source blossoms or exposed honey, if the former source were not available. That being the case, it appears to me that, by setting out robber-traps, bees are punished for their activity, and other bees are drawn into the difficulty. As to Editor Root's remark, "If he [Holtermann] can get a new man who will let no robbing get started he is doing better than we can." Just let me tell you in confidence, friend Root, that, in robbing time, I take good care to be outside myself always, and watch with an eagle eye every thing that is being done; and I find it a very difficult task to impress even *men of experience* with the absolute importance, when working in the apiary in robbing time, of preventing the bees from getting a start.

I remember that Mr. Paul Mickwitz, of Finland, whom the readers of GLEANINGS know, lamented and longed for the experience of a good robbing time in the season that he spent with me. I said to him, "I shall take *mighty* good care that you don't have that experience at my expense," and he did not. He, however, had his wish gratified at another apiary in the district. Of course, I do not speak of special emergencies such as in a queen-rearing apiary. There are some things better than others; or perhaps, I had better say, worse than others, yet neither may be desirable. The article in the *British Bee Journal*, I judged, was intended for the average bee-keeper.

## CONVERSATIONS WITH DOOLITTLE

AT BORODINO, NEW YORK.

### WHEN SHOULD WE EXTRACT HONEY?

"Mr. Doolittle, I had thought of working mainly for extracted honey next season; but from what I have read, it is not at all plain when I should extract the honey from the combs. I find that most bee-keepers, those living in the northern and eastern part of the United States, advocate leaving the honey on the hives till it is all sealed over, some even saying it should be left on till the end of the season, or at least till the flow from clover or basswood is over; while those living in California and in the most of the Southern States claim that it is a waste in time and honey to leave the honey after the combs are half sealed over. Others advocate extracting when few or no cells are sealed, and then ripening the honey in tanks. Do you think locality plays an important part in this matter?"

"Undoubtedly locality does have something to do with this, for under certain conditions honey may be in excellent condition to extract when the combs are only partly sealed over; while under other conditions, and with certain kinds of honey, it would be much better if not extracted until the combs were fully sealed, and, better yet, if left on the hives from one to four weeks longer. These are points with which the expert is familiar, though often overlooked by the inexperienced. You can not go far out of the way by following the advice of such men as Hutchins on, Root, Coggs hall, and others, who advocate leaving honey on the hives till the end of the flow from the nectar-plants which give what is termed 'white honey,' or till the end of the bloom of those flowers which give your main crop of white honey, if the mixing of the different white honeys hurts the flavor and sale of your product. Expert skill in handling extracted honey is not so important in the arid West, as I understand it, as it is in many other localities. Conditions there are naturally favorable to the caring for honey under almost all circumstances; not so, however, in this State and in many other places."

"But some of the writers claim that honey can not be left on the hives until sealed, without materially lessening the crop. They start extracting when the combs are sealed along the tops a little, and from that to the middle. This honey is then allowed to stand in tanks covered with canvas, and evaporated until it attains the proper consistency. It would take the bees from three to five days to complete the sealing of such combs, which time would be nearly or entirely wasted on account of there being little or no room in which to store honey while the remaining cells were being capped over. I remember one of these writers laid particular emphasis on these words, 'The honey can ripen just as well in the tank as in the hives,

and the majority of the bees are not compelled to lie idle, or resort to the brood-combs, to find room to store their honey."

"But such a state of affairs is not necessary, even if such an assertion held good; for the extracted honey producer sees that colonies have sufficient comb room for the storing of honey while the combs which are filled are being sealed over."

"But that would require a large investment for hives and combs that would not be needed by the frequent-extracting plan, as well as not giving as good returns at the end of the season. Another writer said that nearly or quite nine-tenths of all loss of weight caused by the curing of newly gathered honey in the hive occurs during the first twelve or fifteen hours after it is first deposited in the combs.' Now, if this is the truth I can see no reason for leaving the honey on the hives several days longer, thus limiting the storage capacity of the hive, just to allow the honey to lose the one-tenth of weight necessary to ripen it sufficiently for market. Why not extract it and allow the honey to ripen in the tank, thus giving the bees room to work without piling up-hive after hive of combs till the end of the season, this requiring quite a large investment of capital, which, in my case, would have to be borrowed?"

"If it were proven that honey of a nice flavor, equal to that of honey which has been ripened on the hive and prepared by the bees for a month or more could be produced by the tank method, then your reasoning might be correct; but the honey which holds its customers year after year is not, as a rule, honey which is extracted unsealed. The extracting and sale of *unripe* honey is not to be defended, and will react against the one practicing it, for such a one will not be likely to sell this quality of honey twice to the same purchaser."

"I am far from advocating unripe honey; but if honey can be extracted before it is fully sealed over, and then ripened in a tank so that it will weigh not less than twelve pounds to the gallon, retaining at the same time that nice taste and flavor, why do you and others oppose it?"

"Very many have started out with just the same ideas; but, so far as I know, all who have really been anxious to improve the call for extracted honey are now leaving it with the bees till it is fully sealed over, and the most of our really practical extracted-honey producers leave it with the bees till there is danger of having two or more kinds of honey mixed."

"The extracting of partially sealed honey, and allowing it to ripen in a tank, while the bees are filling the combs again, is something which appeals to me strongly, and, if I thought I was scientific enough I should do so, for I am firm in the belief that the expert who uses this method, and thus increases his yield, is to be commended. I would not class him as an unscrupulous person, but a level-headed business man."

"And my advice would be, 'go slow.'"

# GENERAL CORRESPONDENCE

## ABSORBENTS VS. SEALED COVERS.

How Much Packing shall we Use? an Interesting Discussion of the Whole Problem of Outdoor Wintering.

BY LEON C. WHEELER.

*Mr. Editor:*—On page 786 you make the following statement in reply to a letter from Chas. G. Macklin:

"Our experience has been practically the same as yours." "We can not understand why any one should get better wintering results by the use of damp, wet, or (worse yet) frozen absorbents."

It appears to me, Bro. Root, that you are taking an unfair position here, for you assume something which, in my experience at least, is not a fact, and then from that assumption draw erroneous conclusions. Because unsuccessful outdoor winterers find their absorbent cushions damp or frozen it does not necessarily signify that the successful winterer must have those conditions simply because he uses one principle used by the unsuccessful man.

One thing must always be taken into consideration before deciding on any method regarding the handling of bees; and that is, that we are not dependent on one feature of the management alone, but that every condition and every requirement must be the same in all other parts of the hive to make the test complete.

This is none the less true in regard to a decision of the relative merits of the hermetically sealed hive or the one allowing free upward ventilation.

It would give me great pleasure, Bro. Root, to have you come and make an examination of my bees at any time this winter, and see if you can find any dampness in any of them; and there is not one hermetically sealed hive in the yard. You would probably find it to a certain extent in a few of them; and now let me describe the hives in which you would find it.

They are double-walled hives with a two-inch packing space, and with a cover only six to eight inches deep—not far from the dimensions of the Root chaff hive, I believe. If I were compelled to use that kind of hive in this climate I would go one step further than Bro. Root, and say it is impossible to winter out of doors successfully any way.

My father-in-law, who has kept bees nearly forty years, has always wintered principally in chaff hives, and is ranked to-day as one of the three most successful outdoor winterers in this State, and he has never used sealed covers on any of them; but he does not use standard chaff hives. The hive that he uses is made with sides four inches deeper than the inside hive, and a cover eight to twelve inches high—making a pack-

ing space above the bees of not less than twelve inches, and with an outside packing space of from four to six inches.

When he persuaded me to go into the bee business on a small scale six years ago he sent over a couple of these hives. These two colonies increased to six by fall, and the hives were built of the same style for the other four. Although it was my first experience with bees, every colony wintered perfectly with free upward ventilation.

The next year I bought and increased to 27 colonies; and as I had learned quite a lot from reading the bee journals I built some hives on the same plan as the Root hives, with a two-inch packing and shallow covers. Well, I saved the 12 colonies wintered in the old-style hive; and, if I remember rightly, about six out of the fifteen wintered in the new hive. Strange to say, I did not learn my lesson thoroughly that winter; but another winter tried with the sealed covers cooked me, for I lost nearly all of them wintered in those hives, and about half of those in the big hives. Notice, I used sealed covers this time. It is only fair to say, however, that some of them were starvation cases, although they had the usual amount of stores in the fall.

Last winter I packed these light packing hives in a second packing of straw with a roof overhead, and they all wintered, although they did not come out in as good condition as those in large hives.

My experience as a whole with the large hives is perfect wintering in every instance except the one winter when I used sealed covers. With the smaller hives I had imperfect wintering in every instance; but it was worse the winter I used sealed covers.

Now about those damp absorbent cushions. I have in some instances found them damp in those lightly packed hives, but never in the large hives. What makes the difference? Why, it's as simple as falling off a log. The moisture thrown off by the bees condenses on the cold sides of the hive, on the same principle that steam inside of a house condenses on the windows. Why doesn't it condense on the inside walls of the house as well as on the windows? Simply because the outside air hasn't the chance to act on the inside walls with sufficient force to make them cold enough.

Now, this same principle holds good in the bee-hive. The warmer the hive can be made, the less chance for moisture to condense in the hive. The heat from the cluster being that much closer confined, it will take care of that much more moisture. Again, a hive packed with only four or five inches overhead, and no air-space above the packing, allows too much of the heat to escape in this direction, while a hive admitting six or eight inches packing, and an air-space of about the same depth above the packing, retains the heat much better. The packing, being warm, does not condense the moisture, but allows it to pass through it into the air-space above, where it is taken care of without any detriment to the bees.

Only a few moments ago, since beginning this article (the date is January 3), I went out and examined several colonies, and found them all dry and warm.

I should like to see Bro. Root try a few colonies in the hives I have described, and see what the results would be in using free upward ventilation.

Barryton, Mich.

[It rather appears to us that your indictment is not so much against sealed covers as against a too small double-walled or chaff hive—that is, a hive with too narrow spaces between the walls. We have read your article very carefully, and note that you tried the sealed covers only one year with your large chaff hives, and came to the conclusion that they were a failure. You also state, further on, that your experience with sealed covers on the smaller chaff hives was not satisfactory. We will admit that you may be right for your locality when you pronounce in favor of a larger chaff hive with an opportunity for the moisture to pass up through the packing material unobstructed by any sealed cover beneath.

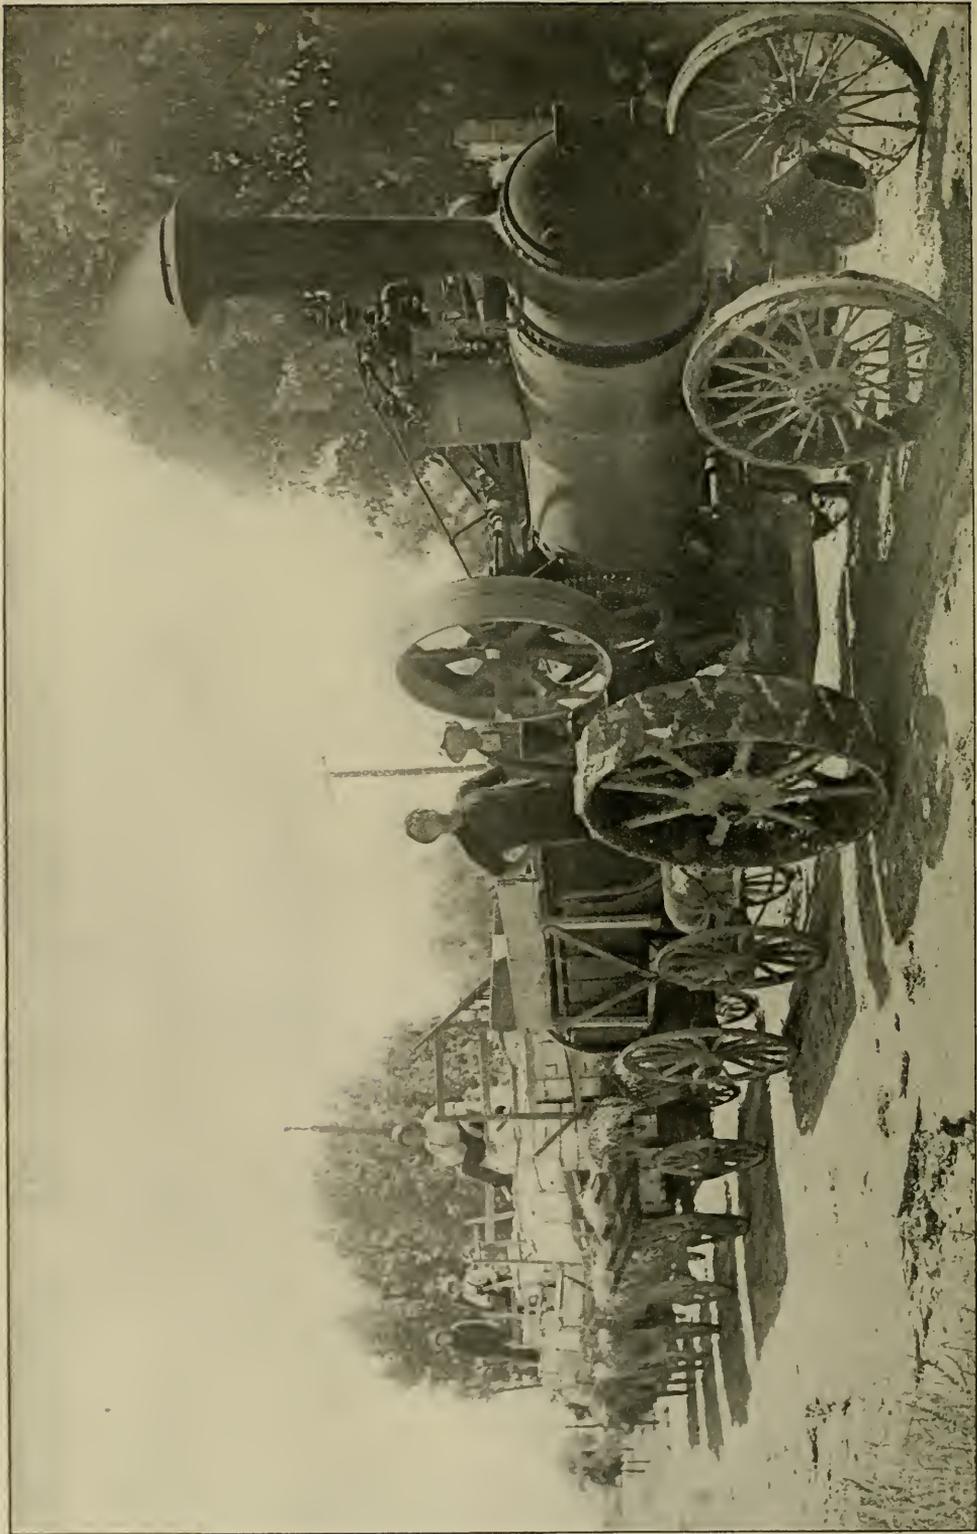

You are probably aware of the fact that the writer had active charge of our bees from the year 1878 on to about 1883. During that time we used the large two-story Root chaff hive. This had walls about 8 inches thick around the brood-nest, and permitted of packing material from 6 to 8 inches thick over the brood-nest, with free air-space of five or six inches on top. For about fifteen years we wintered our bees outdoors in this sort of chaff hive; and from your description we should infer that our hive was even larger than yours. During nearly all of the period mentioned we used absorbing cushions with no sealed cover, and wintered successfully, except the winter of 1881, when our loss was very heavy, as was also the loss of nearly all bee-keepers throughout the country. In the early 80's practically every one who wintered outdoors used absorbing cushions. Taking every thing into consideration, the writer feels that he has had as much or more experience with large hives and absorbing cushions as he has had with the smaller chaff hives and sealed covers. The records show that we have been just as successful with the latter as with the former. The large Root chaff hives cost nearly twice as much as the present chaff hives now in use. When we were using these big hives and absorbing cushions it was noticeable every spring that the cushions were more or less damp, the amount of dampness depending upon the strength of the colony in the spring. At that time it was our custom, on a warm day when the sun was shining, to lift the covers, remove the cushions, lay them on the ground, letting them dry out all day. Just before night we put them back in the hives again. This was a regular program every spring. If we did not dry out the cushions we were likely to find dysentery very shortly.

Later on we began trying the big chaff hives with absorbing cushions and sealed

covers, half having the absorbing cushions and the other half sealed covers. The result for a number of winters left us in doubt. We kept on with our experiments, however, and about this time began using the smaller chaff hive—first with absorbing cushions, and later with sealed covers. The smaller hives with sealed covers gave unmistakably better results than those with absorbing cushions. We also came to the conclusion that the small chaff hives with sealed covers would winter the bees about as well as the large chaff hives with absorbing cushions. The initial cost of the former finally decided us to abandon the big hives altogether. For the last fifteen years we have been wintering outdoors in the small hives with sealed covers, and any one of our apiarists will certify that our wintering has been remarkably good.

You probably fail to take into consideration the difference in climate. It is probably much warmer with us, and it is not so necessary to have a large hive; but a chaff or double-walled hive is an expensive proposition at best. These enormous chaffs especially really add too much to the operating expense in a bee-yard. While it is undeniably true that they are better in a climate like yours, because of the added protection, it does not follow that they afford the cheapest way of wintering, all things considered. Our argument has been this: That if the smaller chaff hives in a given locality with sealed covers will not bring the bees through in good condition the bee-keeper for that locality had *better by all means* adopt cellar wintering. When a chaff or double-walled hive has to be so large, with a packing space of anywhere from 6 to 10 inches in order to winter successfully, it is cheaper to winter indoors. The fact that the majority of bee-keepers in your State, especially the northern sections, winter in cellars or clamps, rather goes to show that this advice is not far from right. From the standpoint of economy it would be cheaper to use single-walled hives and build a repository wholly under ground for sheltering them during the winter than to put that same yard in these monstrous chaff hives. Portland cement is coming down, cheaper and cheaper, and lumber is growing higher and higher.

Having said this much we are not going so far as to say that the sealed cover is better or worse than the upward ventilation and absorbing cushions for all localities. If any one has been successful in wintering with the latter we would advise him by all means to stick to it. We are using at Medina the two methods side by side. Just yesterday (Jan. 12) we went out into the bee-yard and found the colonies provided with upward ventilation and absorbents were wintering just as well as those with sealed covers; but the absorbents were damp, in some cases quite wet. We will admit that, if we were using the old Root Jumbo chaff hive, at this stage of the year the absorbents would be dry. It is only when we come toward spring that the dampness seems to show up.—Ed.]

MOVING FOUR WAGONLOADS OF BEES BY TRACTION-ENGINE IN CANADA.

## MIGRATORY BEE-KEEPING ON A LARGE SCALE.

### A Brief Mention of Some of the Difficulties Encountered when Moving Four Wagon-Loads of Bees with a Traction Engine.

BY R. F. HOLTERMANN.

Migratory bee-keeping, moving bees to various pastures, is, in Europe, a much more common practice than in America. In Europe, so far as I know, the main object in moving bees—aside from moving as a result of changing owners—is to give the bees the advantage of the heather and buckwheat bloom. In the United States, in addition to the objects given above, some have in view moves north and south, for considerable distances, to prolong the honey season.

My first move to bee pastures was some thirteen years ago; and since that, almost every season I have moved sometimes to clover, sometimes to basswood, and sometimes to buckwheat. During these years I have moved many and many a wagonload of bees, many a carload, and also boatloads including a tug and scow, boats propelled by gasoline-engine power and by the wind. This season there has been added to my experience, as seen by the illustration in connection with this article, moving by means of a traction engine.

The most anxious moments of my bee-keeping experience have been spent in moving bees, and I have no doubt whatever that these have resulted in many a gray hair being added to my head. And let me say here, that, unless undertaken in a very small way so that the responsibility and labor are greatly lessened, the chief point to consider is whether the bee-keeper is rightly constituted to bring this work to a successful issue. If he is to surmount the obstacles which lie inevitably in the path from time to time, he must be willing to throw into the work the best his body and mind can produce for the time being. Unless on a small scale this work must, of necessity, be laid out considerably ahead of time, and must, therefore, be carried out regardless of weather and other conditions, at the time set. For instance, if four or five teams are ordered for a certain night (we always try in summer to move at night), farmers often have to make special preparations such as putting hay-racks with straw on their wagon, greasing wagons, shoeing the farm horses in preparation for a long and unaccustomed road trip, etc. These farmers and the bee-keeper perhaps can not readily communicate with one another. This makes it imperative that *all* go, rain or shine, hot or cold. If the trip is made by train or boat the same holds good with the added responsibility of having teams ordered at the other end of the trip. If by boat, owing to the danger of storms, the risk is even greater; and with the danger of having a sail boat, by reason of contrary winds or a calm, left on the water during the heat of the day with the sun to beat down into the boat, the risk

is incalculable. Although I have come safely through every experience, the sail boat for transporting bees is a thing of the past with me. I have seen enough to feel its danger.

In the first carload of bees I shipped I lost forty colonies out of 340; since that, so far as I can recollect, I have lost none by this method of shipping. Thirty-six-foot cattle cars are used. To give the bees air I have used my own invention, a portico to the hive with the sides slightly projecting, and in these projections on the inner side a groove is cut into which a screen can be quickly slipped preventing egress on the part of the bees. The hive entrance is the full width of the hive with a depth of  $1\frac{1}{4}$  inches, and the portico leaves  $2\frac{1}{2}$  inches between the screen and the front of the hive. All the ventilation the bees get during a move is through this screen. My experience would lead me to urge that the bees be frequently sprinkled with water when in transit—the colder the water the better. To spray water all over the hives and the car is also an advantage. The evaporation which follows lowers the temperature. We watch the bees, and when they run about in the portico like a drove of sheep, manifesting excitement, and with their tongues protruding through the screen, we know that there is danger.

In moving bees I avoid using hives where the brood-chambers consist of combs newly built, preference being given to combs wired and toughened by cocoons. If the brood-combs are not heavy with honey and brood, so much the better; but to this latter I pay no attention, simply taking conditions as they are.

During the past summer, having to move bees some forty miles I consulted with the owner of a traction engine, explaining to him that we should have both clay and sand road; and after his assertion that he could draw the load I decided to give the plan a trial.

Some 110 twelve-frame hives with one or two supers on each were loaded on four wagons with racks filled with straw. The engine had also a water-tank, and upon this tank a platform with 1500 lbs. of coal. The bees were loaded, after being interrupted by a thunderstorm which promised much, but let us off with only a slight shower.

About 10 P.M. we moved off at a pace of about  $4\frac{1}{2}$  miles an hour. Every one felt that matters were working very smoothly. The party consisted of Mr. Shurr, the engineer and owner, standing on the engine step at the right hand of the engraving—a man who showed himself a master hand at his work, as we did not have to uncouple our long train even once to turn corners. By his side is Mr. Shurr's assistant. With the bees were Walter Ebert, with whose father I had the bees; next, Louis Held; and on the last wagon, Charles Hatton, of Ohio, whom I had met at the National convention in Detroit, and who spent some time with me to gain greater experience in the production of extracted honey. He said he shone in a long

day's work, and he had his opportunity, as it proved.

Our splendid start did not let me forget that there might be danger ahead, as there had apparently been a heavy thunderstorm, and frequent long trips had given me experience as to variations in rainfall in a section of country; and I knew how slippery clay roads under certain conditions might be. I used to be an advocate of wide-tired wagons until one night, moving bees on slippery roads, we had such wheels on one wagon, the rest being narrow. I followed that wagon on foot for six miles until we passed the clay, and again and again the rear slewed around until at right angles to the road, with every prospect of upsetting unless the driver followed the movement with his horses and the front wheels. From that night to this day I have felt that the advocates of legislation to compel the use of wide tires did not know their business.

The clay roads became more sticky; and, before we knew it, two wagons were almost over a steep bank. With chains to the rack of the wagon, and to a fence post on the other side, we relieved the pressure on the slowly sinking wheel on the other side of the load. A portion of the bees had to be unloaded. Such situations caused delay; and after a time, owing to frequent stops, our water and fuel ran out. The former, owing to a long spell of dry weather, was difficult to get. However, we reached the gravel at last, and our spirits rose; and as we made good time these feelings gave vent through the steam-whistle, as, in the engineer's estimation, worthy objects of salutation were passed on the road.

We thought our difficulties had been surmounted as we passed, like a triumphal procession, through Port Dover. The summer tourists were snapshooting the procession from every direction, thinking, as one expressed it to me, such a scene did not often present itself to the photographer. But when we came to the sand we found it too loose for the engine-wheels to secure a purchase. Here the engineer had reckoned without his host. It would take too much time to describe the troubles we encountered—the broken cable (for each wagon drew from one cable, thus preventing the strain from the rear wagons having to be borne by the preceding), hunts for water for bees and engine, etc. We had a splendid band of workers who made the most of every situation and opportunity. At the most critical time Messrs. E. Trinder, President of the Norfolk Bee-keepers' Association, and Jas. Armstrong, foul-brood inspector for the district, came along.

Seeing the straits we were in, Mr. Trinder gave us wood and water, refusing any pay. Mrs. Trinder prepared food for the party on the same terms, and then the above-named gentleman went ahead and arranged to put the bees at a nearer point, where they were placed by an exhausted party almost twenty-four hours after they were loaded. We all made a solemn resolution never again to

move bees; but within a few days I had another night trip moving bees over the same road by wagon, followed by the shipment of a carload, and then four wagonloads the following week.

Any one moving bees should weigh well the cost, lay well his plans, judge well the chances as to honey, and not only be alert as to every thing going on, but carry the responsibility of the work and set the pace for his help. This means that some will have to carry a load that they are not able to bear. Others may refuse to work so hard, and in this they may have a wisdom superior to the one who practices migratory bee-keeping.

Experience has taught me that every teamster should be continually watched until he has proven himself a careful, thoughtful, and capable man.

Brantford, Ont.

### WHY BEES GNAW COMBS.

**Wax is Needed, and Bees Gnaw the Comb to Get it; they Never Gnaw it Away for the Purpose of Building Drone Comb.**

BY L. B. SMITH.

It is stated by some good authority that if bees are given full sheets of foundation, all worker-sized cells, their instinct and craving will be so great for drones and drone-sized cells that they will often gnaw down a portion of the foundation and rebuild it with drone comb. I have watched this closely for the past 25 years, and have yet to see a case where the bees gnawed down the foundation, and rebuilt it *at once* with drone comb. You will notice that I emphasize the words "at once," for I have many times known bees to gnaw away at least a third of all the combs in the brood-chamber, and later rebuild it with drone comb; but at the time the gnawing was done the bees had no thought of rearing drones or building drone comb. My experience is that this gnawing away of either combs or comb foundation is done at a time when no honey is being gathered; and the more prolific races of bees, such as the Cyprians, Syrians, Carniolans, etc., are much worse at this naughty act of gnawing their combs than are the native black bees or the Italians. I will try to explain further why this is so. Of course, if comb foundation is in any way defective or distasteful to the bees they will proceed at once to gnaw it down and rebuild with both worker and drone comb; but at the time this gnawing away of ready-built combs takes place they will as readily remove drone as worker combs—that is, provided the combs are alike as to age, etc.

The question may be asked why bees gnaw combs, any way. The most common cause is the need of wax. At a time when but little honey is being gathered, bees secrete little or no wax; if a colony has a good queen and plenty of stores, brood-rearing will continue more or less all along, and there is a

Fig. 1.—Scholl's wholesale method of disinfecting by scorching hives, supers, bottoms, covers, etc.

constant call or need for wax by the bees for capping the brood and mixing with propolis to chink up cracks with, etc. At such times bees will not draw on their stores sufficiently to secrete wax; so to supply this want or need for wax they will begin gnawing the combs near the bottom next to the entrance of their hives, and will continue this gnawing until brood-rearing ceases or until a honey-flow comes on; and the more prolific races of bees, as above mentioned, will rear more brood during a honey-dearth than either Italian or black bees, and so, of course, need more wax, and gnaw their combs worse. It makes no difference at such a time whether it is drone or worker comb—it will be gnawed just the same.

Then these combs will not be rebuilt again until a honey-flow comes on and the bees begin to get crowded for room, and, of course, at such times it is only natural for them to build drone or store comb. I doubt whether bees ever gnaw down either comb or comb foundation with the full purpose in view of rebuilding it with drone comb.

We all know that there are other causes for bees gnawing their combs, such as moldy moth-eaten combs, and combs where pollen has caked and hardened in the cells, etc.

Bees here in the South will swarm if well supplied with honey at the swarming season, whether new honey is coming in or not. I have known them to swarm when no honey whatever was being gathered. If hived on foundation at such times they will draw out a small patch in the center of a few sheets, and the queen will start laying in the cells drawn out. By this time the bees will have used up all the wax scales they secreted before they left the parent hive, and they at once start to gnaw the foundation to supply the wax to cap the brood with, etc., and, later, a honey-flow comes on, they become prosperous, and soon more room is needed, and they will build store or drone comb in the places where they had a short time before gnawed away the foundation. The apiarist concludes, when he examines his bees and sees this drone comb where he had put

in full sheets of foundation a short time before, that the bees had gnawed down the foundation for the purpose of building this drone comb, when the truth was they had no thought of building comb of any kind when the gnawing was done.

#### WHOLESALE DISINFECTING OF FOUL-BROODY HIVES.

When this Can be Done Quickly and Cheaply there is No Excuse for Not Doing it.

BY LOUIS H. SCHOLL.

The controversy, both *pro* and *con*, on the question of disinfecting foul-broody hives, has been quite interesting to me; also the stand taken by different ones, the editor included. I want to try to put "the lid" on this matter. My experience in foul-brood work has given me a splendid opportunity to observe some of the things alluded to in many of the arguments. As some argue, it *may* not be absolutely necessary to disinfect hives, bottoms, covers, etc., from foul-broody bees; but as long as we can not put *is* in the place of *may* with absolute certainty, there is left the question whether it would not be best to disinfect our hives, etc.; and we would rather err on the safe side. If there is one chance in a hundred of the trouble re-appearing when we do not disinfect, we run the risk of subjecting all our bees to the danger of destruction by this dreadful disease, and we can not afford it.

I have always been a firm believer in disinfecting not only the hive-bodies, but bottoms, covers, supers, frames, yes, and every thing that has come in contact with foul-broody colonies or used in an apiary of such. The result has been a thorough job, and the cleaning-up of the trouble entirely; whereas we know of cases where the disease has re-appeared again and again in some apiaries where treatment was given by others who were not able to solve the problem as to why

Fig. 2.—Wholesale disinfection of hive bodies and supers. Kerosene is poured down the stack of empty bodies. Fig. 3.—A lighted bunch of straw is thrown in which sets the whole thing on fire. Fig. 4.—In a moment all is a roaring furnace of flame. Fig. 5.—A spadeful of earth below at the draft-opening, and a cover on top finishes the job.

it should always crop out again. In these cases hive disinfection was not deemed at all necessary, and I venture to say that this is one reason why foul brood has to be treated over and over for years, many times in the same apiary. I have never been able to see why some of the small States that have had foul-brood inspectors for many years are not more free from the disease, unless it is that the disease reappears from some cause or other. And at least some cases can be traced back to non-disinfected hives, I feel almost sure.

Fig. 1 shows only one of several places where wholesale disinfecting was administered in my inspection work. All of the methods of disinfecting hives, etc., have been used more or less, but most of them are too slow. Instead of scorching out a single hive-body at a time we stack them up as in Fig. 2 to 5. The empty hives rest on a bottom-board which provides an entrance below to create a draft. A small quantity of coal oil is poured down the inside of the stack, as in Fig. 2. In Fig. 3 a bunch of straw, which was first set afire, is thrown in at the top, falls to the very bottom, and the fire runs up the streaks of oil. The draft upward soon makes all a roaring furnace of heat, which in a very few minutes would consume the entire pile of hives. A spadeful of loose earth to close the entrance instantly and cut off the draft, and a cover over the top as in Figs. 4 and 5, quenches the flames; but the heat remains intense for some little time, thus making splendid work of it. Those stacks in the pictures having covers on them have already been treated.

I used to think it was a waste of time to disinfect frames or save them at all; but experience has shown that it is expensive

to destroy them. In Fig. 6 is shown a large vat over a quickly made trench in the ground in which a rather strong solution of lye and corrosive sublimate in water is heated. The frames, gathered together in lots, are immersed and thoroughly boiled for a short length of time. They come out as nice and clean as so many new frames.

In Fig. 8 the same solution is used in a large round tank which is heated by a steam jet from the upright boiler shown. In our work, all supers that may have been on foul-broody colonies are disinfected just the same. These are immersed with the frames in place, as shown in Fig. 8, a strong spring wire reaching over the top of the super holding them in place. The work is rapidly done in this wholesale way as effectively as in many of the methods that require too much time and trouble, and which, on this account, are too often neglected.

Now, since we can do this work so easily and rapidly and thoroughly, and since it is a risk not to do it, can we afford to say that it is not necessary to disinfect our hives etc.? I say, no.

### ITALIANS SWARMED MORE THAN THE BLACKS.

BY W. C. MOLLETT.

Being convinced by what I had read in the bee journals and books of the superiority of Italians over the common black bees I bought queens of good Italian stock and queened all except two or three of my colonies. This was two years ago, and I was very much pleased with the Italians on account of gen-

Fig. 6.—The frames are boiled in a large vat and made safe to use again.

Fig. 8.—Disinfecting covers and bottoms. The whole super with the inside fixtures and all is lowered into the vat of lye and corrosive sublimate, which is thoroughly heated by steam.

tleness and more pleasing color. They seemed to be of a more industrious disposition, and I had no doubt they would excel the blacks as honey-gatherers; but I was sadly deceived the first year. For some unaccountable reason they seemed possessed of the swarming fever, and swarmed from May till July, seeming to pay no attention to any thing but preparing to swarm. At the same time, the blacks were working steadily and laying up a surplus, and neither of the black colonies swarmed during the season. Two of them filled the supers twice, which is somewhat remarkable for this locality, for it does not have many honey-plants, and some seasons there is little or no honey secured. The Italians would hardly enter the supers at all; some colonies absolutely refused to work in the supers, and just swarmed out as soon as the lower story was full of bees, which would be in a very short time, as they seemed to be extraordinarily prolific. I know that the season has very much to do with swarming; but it seems reasonable to believe that both would have been equally affected. Most of what I have read on the subject says that the Italians are not excessive swarmers; but for some reason these certainly were, and they were said to be of excellent stock, being highly recommended by one of the largest honey-producers in the country. I am in hopes that the past was in some manner an abnormal season, and that the next will show better results.

#### WHITEWOOD AS A HONEY-PLANT.

This tree is usually called tulip-tree, or whitewood, in the North; but in the South it

is almost always called "poplar." The wood is very valuable for building and a great many other purposes, and on this account the trees are becoming scarcer every year. Only a few years ago there were enormous quantities of these trees in most of the southern ranges of the Appalachian region and the foothills of the same region. Now there are only a few inaccessible places in which there are any considerable number of white-wood-trees, and these are growing scarcer year after year.

The whitewood blooms usually about the middle of May, and occasionally, when there are late frosts, the blossoms are almost all killed. This happened in the spring of 1907. There is almost always so much rain that the bees do not have a good chance to work on

whitewood blooms. The blossoms are very large, and are almost exactly like a tulip-blossom, and contain a large amount of honey. The honey is of a dark color, but of very good quality, and brings as high a price here as any kind. I could easily sell thousands of pounds of it at a good price; but there is never enough of it to supply the demand. As the whitewood blooms early it is a great help in brood-rearing, and the bees build up very rapidly where there is even a small number of trees, and are in good shape for gathering basswood honey when the trees bloom. If there had been forest reservations established a few years ago the whitewood and basswood would have been very valuable sources of honey.

#### THE ALEXANDER CURE FOR FOUL BROOD.

#### Another Testimonial as to the Soundness of the Plan.

BY PERCY ORTON.

Dr. Miller's discovery, page 760, Dec. 15, in treating black brood, is ancient history to me, and should be to others if they had practiced what I wrote to you and was printed in GLEANINGS, April 15, 1906, page 507.

I knew how to rid combs of black brood long before Mr. E. W. Alexander reported it; but I was afraid of the State inspector, as two had been to my yard and told me to shake the bees on to new foundation and

Combination paper and wooden winter case being tried out at Medina.

melt up the combs, otherwise I should have reported before.

I have "discovered" that it is not necessary to kill, remove, or cage a queen when getting rid of black brood if you do not care to increase the number of brood-combs.

My treatment is this: Take out one half of the brood-combs in a hive, and push up the follower to within a bee-space of the other combs that are left; put on this body, half full of combs, a queen-excluding honey-board, and on top of that another hive-body. Shake every bee off the combs (that were removed) in front of the lower hive body, allowing them to run in; then put the frames in the empty top hive-body and put on the cover. Leave them for ten days; exchange the lower combs with the upper, brushing all bees into the lower hive-body again. Leave two days as before, and at the expiration of that time put all the frames together below.

Nine times out of ten the colony will be cured if the bees are fairly strong in numbers.

If you are an extracted-honey producer it is much easier to rid the yard of black brood than if you are a comb honey producer. The former has only to brush his bees on to extracting-frames, that have been on the hive to be treated, over a zinc five days or more, according to the time of year, and nineteen times out of twenty the colony will be cured the first time; if not, keep alternating the combs until they are. I never had to change more than twice, even in the worst cases.

I noticed at our bee-keepers' meeting held at Amsterdam that not one person ever took any stock in Mr. Alexander's cure for black brood. Any way, I never heard any one express himself favorably; *but it is a cure just the same*. The secret of it is to keep the queen away from the combs from 10 to 27 days. Some cases are different, and the worker bees will make the cure by removing the cause. Don't kill good queens. Don't shake bees on to foundation alone, as over half will swarm out.

Don't get discouraged. I have had lots of experience during the last seven years; but black brood doesn't bother me any more.

Northampton, N Y.

[See editorial comments elsewhere. It will be noted that Mr. Orton lives in a black-brood district, or what was once that, at least, in the State of New York.—ED.]

### WINTERING OUTDOORS IN WINTER PAPER CASES.

BY E. R. ROOT.

Every winter we are conducting some experiments to test various methods of wintering outdoors. Ever since the winter paper cases came up for discussion we have been using them in a small way to determine how nearly they would hold their own with the regular standard double-walled chaff-packed hives. Experiments thus far conducted seem to show that the paper cases do not give as good results as the regular standard

Paper winter case with chaff-cushion placed on top.

A paper winter case showing the folds of newspaper next to the hive.

hives. While they are, of course, far better than no protection whatever, it is doubtful whether, in our locality, it pays to fuss with any thing of this sort; for the loss in bees, and the greater consumption of stores, will more than make up for the cost of better protection.

During the last year or two we have been trying a combination of wooden winter case and the paper case. The subjoined illustrations will show how some of our hives are prepared. The inner cover is sealed down by the bees. Over the hive are placed several folds of newspaper; over this a large square of heavy wrapping paper, when the sides and ends are neatly folded down and tacked. An ordinary chaff cushion is placed on top, and over the whole is put a wooden winter case that neatly fits over. In the illustrations you will notice how the entrance has been reduced, and the further fact that an Alexander feeder is left on over winter.

We do not anticipate that this combination of wood and paper case will be as economical of stores and of bees as the regulation double-walled hive. Then why do we fuss with any arrangement of this kind? Simply that we may do a little experimenting for the readers of GLEANINGS. If they have any merit at all they may be useful in milder climates than we have here.

## CARPENTRY FOR BEE-KEEPERS.

### Sharpening a Saw.

BY F. DUNDAS TODD.

Here is part of a letter that got me into this trouble. When I had read as far as the middle of it I thought of that joke we used to rattle off as school-children: "Of all the

saws I ever saw saw, this saw is the worst to saw I ever saw," or words to that effect.

There is one feature pertaining to carpentry regarding which a great lack of knowledge exists, and that is saw-sharpening. Can you not give us a chapter on this kind of work? The average farm-saw requires from 50 to 100 pounds weight on it to cause it to "chaw" through a soft-pine board. It is in the interest of the average boy that I want to see an article on how to file a saw.

One of my old business friends has a saying, "When the other fellow puts it up to me I always go him one better," and here it was squarely up to me. I have a perfect mania for very sharp tools, and for years I have taken care of all of them excepting the saws; and these, as soon as the keen edge was worn off, ordinarily by the boys trying to cut through a nail or two, I used to take to an expert. In a general kind of way I fancied all other users of saws did the same thing, even farmers. But I see I have been mistaken. Now that I come to think of it, I can not recall ever having seen a really sharp saw in a friend's house excepting one, and, strange to say, the owner of it was a bank official who sharpened it himself; but I can recall many blunt ones. Now that the problem was up to me I decided to learn how to sharpen a saw, even if it took a week, and included the destruction of one of Disston's best. Well, it took just one day to make me wise; and the best proof is that I have submitted to the critical examination of an old-time carpenter a rip, crosscut, and backsaw, all of which have been under my file, and he pronounces them well done; but he cautiously added, "Not perfect, remember." Being fresh from the work I feel I am in fine shape to tell how it was done, perhaps better than the expert, for he just forgets some little trifling point that means so much to the novice.

My correspondent wants especially to know how to treat a saw that has been filed out of order. Honestly, I did not expect to be able to handle this problem with credit; but my first attempt, just because of the want of information regarding a trivial point, resulted in a saw very badly filed out of order; and for the best part of two hours I worked hard on what was really a ticklish job in dentistry, for that saw needed a new set of teeth. It got them, and I am rather proud of the job.

For sharpening an ordinary handsaw one needs four tools—triangular file of tapering shape; flat file; a saw-set, and a saw-clamp; My correspondent speaks of different sizes of triangular files, evidently being of the opinion that the various sizes will give different angles, but this is not so; for, no matter what the size of the tool, if we break it straight across, the surface will be an equilateral triangle; and any one who has studied geometry knows that, in such a triangle, each angle is of the value of 60°.

The flat file is to be used for jointing—that is, making the teeth all of one height.

The set is used for bending the teeth side-wise alternately, so that the cut made by the teeth will be slightly wider than the blade, thus permitting the blade to work freely.

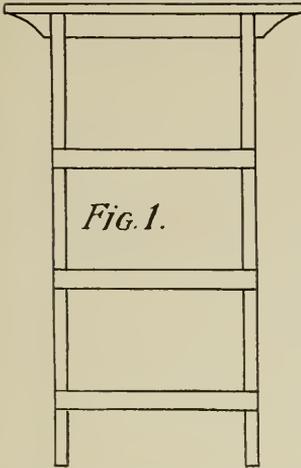

Fig. 1.

The clamp is to hold the saw in position while it is being treated, and is indispensable. I know whereof I speak, because in a fit of smartness I held the saw, on my maiden effort, in the bench-vise. I have just finished making a clamp like one I borrowed, every bit of the sawing being done with tools of

my own sharpening, which worked cleanly and smoothly; so before the reader does any thing else he must make a saw-clamp. Fig. 1 shows the front elevation.

The classifications are: uprights, 2 pieces, 2x4x50; cross-pieces, 3 pieces, 1x4x21; vise, 2 pieces, 3/4x2 3/4x30.

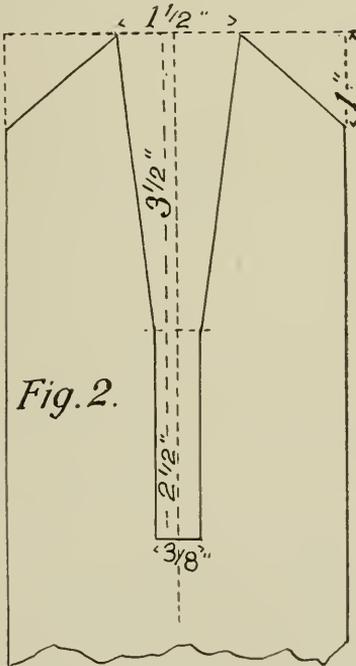

Fig. 2.

The lengths of the uprights will depend upon the height of the man who is to use the clamp. I find in my own case it is about six inches shorter than the distance of my armpit from the ground.

Begin work on two 2x4 stuff by drawing on the face at one end of each piece the design shown in Fig. 2; then saw out the

center piece and cut off the corners; then nail on the three cross-pieces. The two pieces that form the vise are to be held in the V-shaped cut, and must, therefore, be planed to a suitable shape.

Fig. 3 shows the pair in cross-section with exaggerated space between. To lay out the work on one face of each piece, draw a line 3/4 inch from an edge; then on the opposite edge draw a line right down the middle. Plane the marked face until the new surface is bounded by the pencil lines; then plane the other edge until a new surface extends from the pencil-line to the margin of the unmarked face.

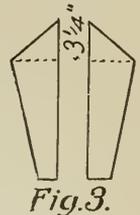

Fig. 3.

Last of all, sufficient from the ends of each piece must be cut away to give room for the handle of the saw. Fig. 4 illustrates this.

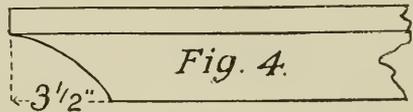

Fig. 4.

When you use the clamp it is better to be out of doors, because you will need lots of good light. There is no chance work in filing a saw; you must know exactly the shape of tooth you want, and see that you get it; so, set your clamp up against a fence and rope it tight to the railing so that it can not move.

SAWS AND THEIR TEETH.

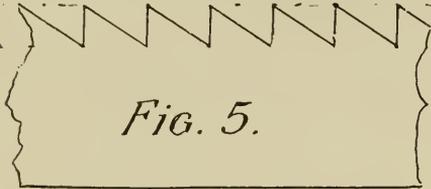

The use to which a saw is to be put determines the shape of its teeth; consequently, for the proper sharpening of any particular saw one must know to what purpose it is to be put. This article is not intended to cover the whole field of saw-sharpening, but only such phases of it as may come within the scope of the average bee-keeper or farmer. The essential saws for such a one are cross-cut, rip, and back saws, for soft or medium hard woods, and buck-saw for the firewood pile; hence only these will be considered here.

The rip saw is used to cut in the direction of the wood; the other three, across the grain.

A saw-tooth has two functions—paring and scraping. The rip saw acts like a chisel, each tooth cutting out a piece of the fiber, which lodges in the throat of the tooth and is carried forward until free of the wood, when it falls to the ground. Since one tooth alone is responsible for each bit of fiber, both sides of each tooth must be equally sharp; in other words, the forward face must be at right angles to the body.

So much for the paring action of the tooth. Let us now consider its duty as a scraper. Scraping is done with a sharp tool held at right angles to the surface that is being operated upon. The bottom of the groove in which the saw runs is the surface that is be-

ing scraped, and this surface coincides with the line formed by the teeth of the saw; therefore, to get the teeth perpendicular to the surface of the bottom of the cut we make them perpendicular to the general

*Fig. 5.*

line formed by the points of the teeth. Fig. 5 illustrates the teeth of a four-point rip saw, such as is used for soft woods. The angle which the front of the tooth makes with the general line is called rake, hook, or pitch. In this case it is perpendicular.

Right here it may be as well to explain that saws are classified by the number of "points" of teeth that come within the compass of one inch. The number of teeth is one less than the number of points. In most saws the number of points is stamped on the blade below the handle. For medium-hard woods a five-point rip saw is best, the teeth being dressed like the four-point.

#### CROSSCUT SAWS.

In cutting across the grain the fiber can not be wedged out as in ripping. It must be severed on each side as if by a knife-cut, so we see it takes two teeth to cut out each little bit of wood fiber that comes away. The front or cutting edge of each tooth must, therefore, be brought to a sharp edge like a knife — with this difference, however, that the bevel must be on only one side of the tooth — the inside. Again, we all know that it is very difficult to cut a piece of wood with even a sharp knife when the blade is kept at right angles to the direction of the stroke.

However, if we advance either the point or the handle ahead of the rest of the blade, cutting is much easier. For this reason the pitch of the tooth of a crosscut saw is generally about 60°. The only exception a farmer or bee-keeper is likely to meet with is the pruning-saw, where the pitch is usually almost perpendicular, like a rip saw; but the edge is beveled like a crosscut saw. The upright pitch is permissible because of the soft green wood it is used upon. A six-point crosscut saw is the best to use on soft wood where rapid rather than fine work is required. For medium hard wood a seven-point saw is better, while a general-purpose bucksaw has four points. Experts make a slight difference in the amount of bevel that is given the teeth of different crosscut saws; but for general use they may be all sharpened the same way.

Before dismissing this general subject of teeth it will be well to point out that, since both edges of each tooth are beveled, when we look sidewise at the tooth of a

crosscut saw we see a little one inside of a big one. The upper corners are joined by a straight line; therefore when we turn the point of the saw toward us so as to get a profile view of a tooth we find it looks like Fig. 7, and two adjacent ones appear like Fig. 8. In a well-sharpened saw this groove should show all the way down when one sights along the edge toward the light. The more perfect you can make this groove the nearer you approach perfection in sharpening.

#### JOINTING THE SAW.

The first step in sharpening a saw is to joint it; that is, bring all the teeth to a uniform height. This is very important, for if one tooth be just a little above the general level, the saw will stop with a jerk right at that point. To test this, lay a bit of flat wood on the saw-bench and run a gentle stroke across the edge. When the saw suddenly stops, mark the spot and you will almost certainly find a high tooth right there.

I will suppose your saw firmly held in the clamp, the grip being tightened by hammering the vise firmly. Take a ten-inch sharp flat file without a handle; lay it on the teeth with the point toward the point of the saw and pass it along the teeth, repeating until all are of a uniform height. In a bad case of uneven teeth you may have to make quite a vigorous application.

#### SETTING THE TEETH.

As already said, setting consists of bending the teeth alternately from side to side. The flat side of the tooth is bent outward. The amount of set is determined by the size of the tooth and the nature of the job. Soft woods need more set than hard woods; wet woods more than dry. But use no more set than is actually necessary; for the more set, the more wood is cut; therefore more force must be applied. But whatever be the set it must be uniform throughout; but, luckily, this is easily got by the adjustable sets on the market. Using a Tainter's saw-set I find excellent results when the anvil is turned to No. 2 for the back saw, No. 4 for the seven-point hand saw, and No. 5 for the rip saw. All the set should be in one-half of the tooth, and should never reach to the body of the blade. In setting, begin at the handle on one side and finish that side before tackling the other.

#### FILING.

With a saw in fair condition the safest rule to follow is to put a new surface at exactly the same angle it had before. Push the file with a slow and steady stroke so as to use the whole length of it, always keeping the downward pressure uniform throughout the whole stroke so that the action on the tooth will be uniform from top to bottom of the tooth. On the return stroke, either lift the file clear or allow it to rest very lightly on the saw. Two strokes are usually sufficient for such a tooth as one finds in a six-point saw, while only one is usually enough

on the small tooth of a back saw; and, speaking of files, do start with a new one, keeping it clean and well oiled.

But suppose you are starting out to work on a saw that is badly out of order, such as my correspondent described—one that has been filed all kinds of ways, and set without any system; then you will have a job on your hands that will keep you busy for quite a while. First, see that your saw is so set in the vise that the lower part of the finished tooth will be very little above the level of the vise top—only enough for the vise to clear it, and you will then have a guide for the depth of the cut. Theoretically you are to work upon only one tooth at a time, but I find my file is busy with one on each side. Which will be filed the more will depend upon how the pressure is applied; and this gives one a chance to correct an uneven width of teeth; so when you apply the file to any particular tooth, compare it with the one on the other side of the file, and press hardest against the wider one, letting the other take care of itself. You will thus be able to get uniform width in the teeth of the saw.

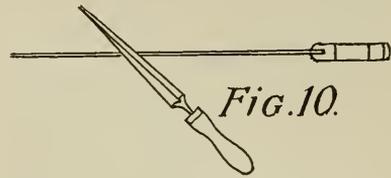

THE TOOTH TO WORK ON.

Start work on one side at the end nearest the handle, and file each alternate tooth; then reverse the saw and file the remainder. You will probably be in doubt as to which tooth you are to work upon. I know I was. It is the one that is bent away from you, the one in which you can see the little tooth inside the big one; and you are to work on the face next to the point of the saw. So when the handle of the saw is on your right, the tooth you are to file will also be on the right of the tool; when the handle is on your left, the tooth will be on the left of the file.

ANGLE OF FILE.

The angle at which the file is held is important. We have two to consider—first, the angle with the perpendicular face of the blade; second, the angle with the line of the teeth. The first is always at right angles; so if the clamp is standing perfectly upright, then the file will be horizontal. The second angle is determined by the amount of bevel wanted on the teeth. In the case of a rip saw, where a square-pointed tooth is wanted

Fig. 10 shows the angle when we look from above. The cant of the file will depend upon the rake you want to give the tooth. With crosscut saws the top face of

the file should be level in both directions; with the rip and pruning saws the face of the file working on the front surface of the tooth must be upright.

In working over an old saw that is in bad shape, bend all your thoughts in getting uniform depth of cut, width of teeth, and angle of bevel. Do not worry at this stage about the height of teeth or the angle of slope shown in Fig. 7; for if the other three are right, these two will probably take care of themselves, provided always the file is kept level and at the proper angle with the line of the teeth.

An old proverb says that an old violin is good enough for a beginner to practice on. Of course it is; for it is a better instrument than it was when first made. But an old bent saw with twisted teeth, sometimes wanting a few of these essentials, is not the best tool for first experiments in saw-sharpening. The possessor of a good saw with many broken teeth should send it to a saw-cutter who will strip off the old teeth and punch new ones in the new edge.

Let me conclude by giving the dimensions of saws that are recommended for such work as happens around the average apiary or farm:

	Length	Points to inch
Rip saw	28	4
Hand or crosscut	26	7
Tenon or back	10 to 14	10
Keyhole or compass saw	14 to 18	9 to 12

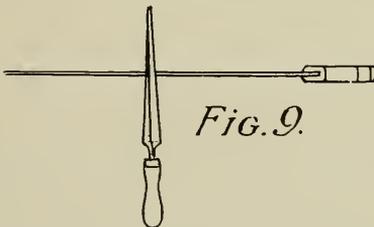

Victoria, B. C.

A STRUGGLE WITH EUROPEAN FOUL BROOD.

The Removal of the Queen and the Introduction of a New Italian Queen Effected a Cure; Goldens Preferred to Three-banded; the Alexander Method Followed.

BY EDGAR WILLIAMS.

I should like to give you my experience with European foul brood or the so-called black brood. The winter of 1903 proved to be a very severe one on bees in this locality. Most bee-keepers lost from 75 to 100 per cent of their bees during the winter and spring. My bees were wintered out of doors in single-walled hives packed only on top. I saved only four weaklings out of eighty good colonies the previous fall. Whether this had any thing to do with the disease I can not say—probably not. I am simply telling it as

the file will be at right angles to the length of the blade. In Fig. 9 we are supposed to be looking down upon the teeth of a rip saw from above, and we see the file working at right angles to the line of the teeth. In crosscut saws, such as have been described, an angle of 45° is about right.

a prelude to my story. I purchased three more colonies that spring, and moved them the fore part of June. They were perfectly healthy, as were the four I had wintered. The raspberry commenced to bloom, and it was followed by white clover, so that my seven weak colonies built up rapidly.

About the first of July I decided to begin preparations for increasing my apiary. I moved one colony to a new location and placed a set of combs on the old stand for the old queen. If the old colony had plenty of young bees left I intended to let it rear its own cells. On looking at the old brood a day afterward I was somewhat surprised to find that nearly all the bees had deserted it. I took away most of the sealed brood and gave it to other colonies for fear it would chill, massing the frames left containing partly unsealed brood in the center of the hive. It was now not much better than a nucleus. About ten days later I made an examination. The sealed brood had mostly hatched, but that which was unsealed had died and lay untouched in the cells. Half of it had turned to a dark-brown mass. I thought it was chilled brood, and it *might* have been, for the colony was perfectly healthy. When I divided it I gave the frames to several of the other colonies. The honey-flow continued a while longer—about ten days—and the dead brood practically disappeared. After the flow had ceased I noticed a large quantity of dead brood in several hives. I began to think something was wrong. Several in the neighborhood who kept bees were consulted. They had never noticed any such thing except an occasional cell, therefore they were inclined to think it was poisoned or starved brood, so I did nothing. Being anxious for increase that year I formed nuclei, raised queens, and then strengthened the nuclei by drawing brood from the stronger colonies. The seven colonies were increased that year to thirty, all of which were inoculated with disease.

#### GOOD PROSPECTS FOR 1905.

The bees wintered well, as I lost only three colonies out of thirty. The first batch of brood the bees reared appeared to be healthy, and I thought the disease had disappeared. This is something I have often noticed with the disease. The first lot of brood raised in the spring is, to all appearance, healthy. It is the second lot, or after that, when the disease begins to appear. But soon I noticed it in a few colonies, and by the latter part of May every colony but two was badly diseased. Some showed very few healthy cells. In some cases it seemed to affect the bees. Some colonies that had prepared to swarm, in a few weeks had scarcely enough bees to cover the brood. These, of course, were exceptional cases. Two colonies remained healthy. One was a hybrid; the other colonies left showed three yellow bands, although at that time I had introduced no new blood. The rest were all hybrids.

I sent a sample of the brood to the A. I. Root Co. They pronounced it pickled brood, or possibly foul brood, and advised me to

give the bees the McEvoy treatment. I decided to follow their advice and do a thorough job. So on the first day of June, 1905, I shook all the thirty colonies, except the two healthy ones, on frames with starters. As I had no tight building to handle the combs I carried the whole 23 set through our dining-room, up a flight of stairs, through a hall, into an attic. As luck would have it, mother did not notice the honey and bits of comb that got on to the stair carpet until the combs were all in the attic. Shaking the bees and carrying the combs into the attic occupied a whole day, and a hard day's work it was.

That evening I went to work extracting the honey out of the combs. Part of it was candied and would not come out. I worked past midnight, took a "lay off" next day, and worked past midnight the next night before I got the stuff extracted.

Next morning I built a fire under the big iron kettle, went up into the attic, cut the combs from the frames, put them in sacks, and carried them down and put them into the kettle to render into wax. I had just completed stacking the combs, and had part of them in the kettle. The wax was about ready to boil over when mother came to the door and informed me that the attic was full of smoke—the house must be on fire. I hurried into the house and up into the attic, distinctly remembering that, the *day before*, I had had the smoker up there driving some bees out of doors that had clustered on the windows.

Pierpont, Ohio.

To be continued.

## THE VARIATION IN ORANGE HONEY.

BY EDWIN G. BALDWIN.

*My dear Mr. Root:*—You will note in the article by Mr. H. F. Hart, of Alabama, page 738, Dec. 1, that he names titi and black tupelo, sweet gum, gallberry, and loquat as possible sources of contamination with the pure orange nectar. I am much obliged to him for his kindness in calling my attention to what he believes are possible sources; but locality has so much effect, he naturally supposed that, because we live in Florida, we have all the trees, shrubs, etc., that are to be found anywhere in the State, and have them right here in range of our bees at DeLand.

As a matter of fact and interest, the titi and black tupelo do not extend further south than the northern end of Lake George, northern end of our county, sixty or more miles from us. That is the southern limit of their growth. The loquat is here in fairly large numbers; but it is now in bloom, and will be till early January. It is in fruit, not blossom, by the time oranges come into blossom, and can not possibly be a source of any of the honey in the supers at orange-blooming time unless it be carried up by the bees later in giving the queen room, as stated in my article on orange honey in your columns.

The gallberry (our holly) blooms, by actual tabulation, from the 23d of April (the earliest noted) to the 11th of May, the average being the 5th of May or thereabout. It is too late to come into our orange crop, as we extract as soon as the last orange-blossoms are gone. That leaves but the sweet gum in the list named by Mr. Hart. If our bees worked on it here it would be a source, I admit. But I have never, in all my observations, seen any bees on sweet gum in our section. Whether it does not yield honey, and whether climate and soil can be accountable, are questions I have not yet been able to determine. I have sent another sample of this year's orange-blossom honey to Mr. Younge, of Washington, and await his verdict on the pollen-grains with deep interest. By the way, I sent him a sample of California orange honey (so called), and was not surprised to hear that there were no clear-cut grains of orange-blossom pollen in it, for I had already made up my mind that it had very little if any of the real orange. It did not have the taste nor color nor odor; and the pollen grains only confirmed the other attributes. As I wrote Mr. Hornor, of Jenkintown, it is probable that much light-colored well-flavored honey from California is sold under the name of "orange honey" for the sake of the suggestiveness of the term, just as much tupelo honey from Florida is sold by that name in New York and other cities, as I happen to know from talking with large dealers there; at least this was so before the passage of the pure-food act. How it may be now, I do not know; but this sample of honey from California was surely masquerading under the title of a honey that it did not deserve. Large shippers of East Coast oranges from Florida tell me that much fruit from that section is sold as "Indian River Oranges" just because that particular region happens to produce the finest fruit grown. May it not be so with some of the honeys from California? If so, ought not the pure-food act to have a word to say in the matter?

Deland, Fla.

### SWEET CLOVER.

---

#### Profit in Growing, Sowing, and Cultivating it, and How to Make it a Most Valuable Crop.

---

BY R. L. SNODGRASS.

---

To produce the first crop of sweet clover, sow 20 lbs. of the seed per acre any time between Dec. 1 and Feb. 1, as the seed always germinates best if it freezes a few times in the ground. About the first of September it is well to turn stock on the clover, and pasture it until the first of December, as it will keep green until this time, and even later.

The following spring one may pasture it for two or three weeks; and if it is not grazed too long it will give a good crop of

bloom and seed; if it is pastured too long it will not grow so tall, and the blooming and seed crop may be cut a little short.

As soon as the seed crop is cut, plow the ground and sow to buckwheat or millet; and as soon as either of these is harvested the ground is in fine condition to disc to wheat. I do not consider it advisable to sow more than half a bushel to three pecks of wheat per acre if a good stand of sweet clover is desired the following spring, as too heavy seeding of wheat tends to smother out the clover. If the wheat is not too thick the sweet clover will come up in the wheat from the seed, and the following year another good bloom and seed crop can be produced. One can again go through the same routine as before. I have the best stand of sweet clover that I ever had, that I managed in just this way.

It always pays to plow up a field after a seed crop has been cut, for a good stand is never secured after a seed crop has matured, as the old plants smother out the young ones. Hence I recommend plowing it up; in fact, the clover does better if a field is plowed up every two years.

Any one managing a field in the way I have described can well afford to pay \$5.00 per acre, cash rent.

There is no other clover that is such a soil-renovater as sweet clover. I have been pasturing my clover ever since one month after I cut the wheat. When I turned my cows on it they doubled the flow of milk, and it is still green as it can be at this writing, Dec. 5, and my cows are still grazing on it—the white clover. I have also a fifteen-acre field of the yellow variety on rented ground that is about one foot high, and just as green as in mid-summer. I haven't turned the stock on this yet, but expect to do so soon. I prefer the yellow variety to the white, as it is an earlier bloomer and makes more pasture, as it will stand closer grazing. The hay is also much finer, and cures more quickly, and therefore is ready to stack much sooner than the white; and I believe, too, that the stock eat it more readily.

Now, the most important feature of it all is that it is an earlier bloomer by two or three weeks than the white or alfalfa either, and consequently it puts the bees in good condition for the alfalfa honey-flow; and if the first crop of alfalfa fails to bloom, as is usual in Kansas, the yellow sweet clover lasts until the second crop of alfalfa is in full bloom. I had 100 colonies last season that had only eight or ten acres of the yellow variety to work on, and my colony on scales gained about 2 lbs. per day for 30 days, on the yellow variety of sweet clover, between the first and second blooming of alfalfa. Now, if this will not put all colonies in shape for the second blooming of alfalfa I don't know what will unless it is heavy feeding, and that is rather expensive and not so easy. And in addition to the benefit my bees and stock derived from it I secured about 2000 lbs. of cleaned hulled seed.

Augusta, Kan.

## COMMERCIAL QUEEN-REARING.

### Are Not Some of the Modern Methods to Blame for so Many Poor Queens Sent out by Queen-breeders?

BY J. L. BYER.

As I have never reared a single queen by the artificial methods now in vogue it may look like sheer presumption to make any comments on the subject of commercial queen-rearing. However, though I have not reared any queens I have nevertheless bought a good many; so, by way of apology for my statements, I will talk from the standpoint of the consumer rather than from that of the producer, in so far as the trade in queen bees is concerned. At the Ontario convention, held in Toronto last November, much time was taken up in discussing this very important phase of the industry, and the members had the pleasure of having two of our commercial queen-rearers present, and of listening to each of them as he gave a practical and lucid address.

In the discussion that followed these addresses, many of the members commented on the great difference in the queens received at different times, even from the same breeders. While it was generally admitted that there is always considerable variation in queens reared by the ordinary methods, yet the idea seemed prevalent that the variation is much more pronounced in queens reared under the new commercial methods.

J. W. George, page 763, tells of the double-grafting method used by some apiarists in California to ensure the generous feeding of the queen larvæ; and the question arises as to whether queens reared by modern methods are not apt to be neglected in this line. If that is the case, it seems reasonable to believe that poorly fed larvæ might account for a lot of the poor queens that are undoubtedly sent out by queen-breeders. This point was brought out in the convention, and I mentioned the fact that, in my experience, the great majority of queens reared under the swarming impulse certainly do not suffer in this respect, as nearly all cells have a surplus of royal jelly left in the base after the queen has emerged. Whether this is the case with pure Italians or not I can not say, as I do not remember having had more than two swarms from this race of bees. The reasons for this are that I use large hives, and nearly all our bees have Carniolan blood.

From a recent experience I have had, I feel convinced that sometimes *something* out of the ordinary occurs at times, even with the best queen-breeders, with the result that a whole batch of poor queens is sent out at the same time. For a number of years I have bought queens from a man who has an international reputation, and nearly always these queens have turned out well—so well, in fact, that I have repeatedly recommended these queens when out on inspection work. To make a long story short, in July, 1908, I

received quite a large bunch of queens from this breeder, for my own yards and for a yard belonging to a bee-keeping friend. All wintered well, and this spring appeared to be in ordinary condition as compared with the rest of the bees in the same apiaries. As to actual results, strange to relate, there was not a single queen in all the number received by either of us that was worth much more than the cage she came in. This is, of course, comparatively speaking, as some of the colonies with these queens did store as much as 50 lbs. of honey in apiaries where the general average was around 150 lbs.

Now, while I am not going to say that this batch of queens had been partly starved while in the larval stage, yet conditions at the time of their rearing were wrong in some way, else why should the whole lot have turned out so worthless when, as a rule, queens received previously had given a good account of themselves.

I leave the problem to be solved by those who are in the business—particularly to the one most interested. In this case I deemed it my duty to tell the queen-breeder how his last lot of queens had turned out, and his letter in reply says that he can not understand it unless it was caused by the drouth. Presumably he refers to the drouth of this past season; but as to why it so affected his queens, and not others in the same yard, is not explained. I frankly confess that the answer received from him did not tickle my vanity any, as I decided that he must have a very poor opinion of our judgment in the matter to advance such a reason.

### DOES EUROPEAN FOUL BROOD VARY IN VIRULENCE IN DIFFERENT LOCALITIES? GOLDEN BEES MORE IMMUNE.

Dr. Miller's account of his dealings with black brood will be read with interest by many here in Ontario at the present time, as we have in our province an outbreak of this disease. From my experience with this plague I can not but believe that the disease varies greatly in its virulence, and what we have here in Ontario is much worse than the brand at present around Marengo, Ill.

Certain it is that the Alexander system of treating the disease is worse than useless here, as it simply takes up valuable time and gives no good results. Even after the most thorough purging, it will reoccur in a great many colonies; and at present Mr. Warrington Scott, the inspector in the infected district, believes that only by thoroughly Italianizing all stocks is there any chance of getting rid of the pest. More than that, he will not stop with the ordinary Italians, but insists now on the goldens as being the only ones likely to keep immune from the disease. Mr. Scott is one of our most thorough apiarists, and has lost thousands of dollars from black brood, so his opinions are worth taking into consideration. Personally we have been rather prejudiced against the very yellow bees on account of their poor wintering qualities, especially when left outdoors; but if they are immune to black brood, that cer-

tainly will hide a multitude of sins, especially in sections where the disease is already established.

#### IS HONEY-DEW AN EXCRETION?

I for one shall be more than pleased if D. M. Macdonald's view, page 763, Dec. 15, is established as to honey-dew not being an excretion. I hope he is right, so much that I almost believe already that his view will be substantiated. The subject of honey-dew has, with my present knowledge on the matter, always been the *one* subject that I did not want to explain to the prospective beekeeper, and especially so to the buyers of our honey. As the editor pertinently remarks, entirely too much has been said on the excretion phase of the question, which, after all, now seems to be a debatable question; and in the light of friend Macdonald's opinions it may prove to be a libel on the honey industry.

Mount Joy, Ont., Can.

[There is no denying the fact that different batches of queens will vary somewhat, according to the season. Any queen-breeder of experience knows that it is much more difficult to rear good queens during a drouth than during a honey-flow. Practically all of our best breeders have found it absolutely necessary, during a dearth, to feed copiously those colonies that are rearing cells. Some even go further and make the cell-builders queenless, broodless, and combless for a few hours, feed copiously, and then give them one comb with a bar of grafted cells. No matter how severe the drouth, such bees will build as fine cells, and supply them as copiously with royal jelly, as bees directly under the swarming impulse.

But it sometimes happens that a queen-breeder who has been depending upon the natural honey-flow gets caught. Before he knows it the supply of nectar has suddenly stopped. Unless he is able to take a "stitch in time" by feeding the cell-building colonies, the queens from those cells will be of low standard. While we do not know that this was so in the case of the queen-breeder mentioned, it might have been.

Regarding European foul brood, we doubt very much whether there was any difference in its virulence in different localities; but we do know that a difference in the strain of the bees does have a marked influence in the matter of cure. It is possible that, in some localities, there is more of the Italian blood than in others. It is possible, also, that there is a strain of blacks, with just enough of Italian blood, that will resist the plague as much as or more than the Italians. Dr. Miller uses hybrids very largely. It will be remembered that he has been working for years to produce an extra energetic strain of bees without regard to markings. That he has to a great extent been successful is borne out by the fact that he has secured high averages per colony. This was especially true in 1908. Now, it is possible that the Dr. Miller strain of hybrid hustlers also have a great resisting power against Euro-

pean foul brood—as much as or more, perhaps, than some of the good strains of Italians.

Whatever the merits of the Alexander treatment, or the treatment as modified by Dr. Miller, it would seem to us that it would be wise to combine the McEvoy and the dequeening process of Alexander and Miller. Speaking about Mr. McEvoy, it will be noted that, in the editorial department elsewhere, he says Dr. Miller's experience in the matter of treating European foul brood is quite in line with his own. Mr. Percy Orton, of New York State, who appears to have had a large experience, claims that he has known all along that the Alexander method of treatment, even before Alexander gave it to the public, was effective.

We shall be glad to get reports from others who are able to offer testimony on the effectiveness of the Alexander plan of curing black brood. We are not seeking favorable reports only; we want the *unfavorable* as well. Mr. Orton feels that European foul brood is easily handled, and it certainly is if the Alexander-Miller form of treatment or the one used by Mr. Orton is effective.—ED.]

#### SOME OBSERVATIONS ON THE HABITS OF THE HONEY-BEE.

##### Bees Gathering Wax.

BY WM. M. WHITNEY.

*Mr. Editor:*—Dr. Miller, in *Stray Straws*, July 1, refers to bees being seen loading their pollen-baskets with wax which they found outside the hive. It has been a common observation in my yard, when bits of comb outside have sufficiently softened by the sun to be worked; also, later in the season, I've been very much amused watching the bees gathering propolis left where the sun's rays had softened it. I have many a time seen them filling their baskets with it, glistening in the sunlight like little brown beads. My entire time for thirteen years and more has been spent in carefully watching the bees.

##### HOW TO TELL FROM THE OUTSIDE WHETHER A COLONY IS PREPARING TO SWARM.

The question is sometimes asked if it is possible to tell from the outside appearance of a hive whether there are indications of swarming before it actually occurs. This question, I think, was asked at one of the meetings of the Chicago and Northwestern Association, and it was generally conceded that there was no way to tell. Notwithstanding all this, I believe there are outward signs of swarming; but it requires careful watching to discover them. There is a marked difference in the appearance of young bees out at play, as it is termed—marking their location—from that of old ones apparently doing the same thing. When one sees *old* bees during the swarming season come out and fly before the hive like young bees at play (excepting at a time when they have

been kept in by a spell of bad weather, at which time they are simply marking their locality anew) and settle down, then come out again in the same way, you may conclude that, in a very short time, a swarm will emerge—often within a few minutes; but sometimes an hour or two may elapse unless a sudden change of the weather occurs to prevent, which, of course, will delay it till favorable weather. At the yard at Barrington a few days ago two colonies which I had predicted, from outward indications, were liable to swarm, came out in a drizzling rain, and we hived them while it was raining. This act of flying in front of the hive is often repeated several times; and when it occurs in quick succession, put your ear to the hive and you will be likely to hear an unnatural uproar all through the hive, which immediately precedes the grand rush.

#### MEMORY OF PLACE IN BEES.

I was very much interested in articles under head of "Are Bees Reflex Machines?" and especially in that of July 1, "Memory of Place in Bees." Observation and experience in the bee-yard have taught me many things which have a direct bearing upon the matter of orientation; hence the special interest in the subject under discussion. It is a well-known fact that, when bees swarm, if the queen does not follow they ordinarily return to the parent hive, or, in other words, to the old stand; yet it is easy to deceive them, if the parent hive is the end one in a row, by putting an empty hive at the end beside it, into which they will go, although their own hive stands not a foot away. Their memory recognizes the end hive as theirs. So it is with bees returning from the field to an end hive in a row. If another is placed at the end beside it they will persistently try to enter the end one. An experiment of this kind was made less than three weeks ago at a yard where a young apiarist was being instructed in the management of bees. They were flying freely, and in less than five minutes the front of the hive and alighting-board was covered with bees trying to enter the wrong hive, while theirs was not 18 inches away. Again, who has not tried the experiment with bees that have had the habit of using one end of the entrance to the hive of forcing them to use the other end, and watched their persistency in trying to enter at the old place? All this seems to be the result of memory purely. Practical bee-keepers, however, have learned that, by confining them for a short time, say three days, they forget their past location—hence the ability to do many things in the manipulation of the hive which otherwise might be impossible to accomplish.

I am convinced, from watching bees in my own yard, that where hives are put in rows, and near each other, and where there are no trees, shrubs, or other landmarks to mark location, there is much more mixing than is generally supposed—especially if bees are of the same strain, and more particularly with young bees that have not clearly marked their location, and that many valuable

young queens are lost in this way. I say of *the same strain*; for my bees, being Italians, no black bee would be permitted on the alighting-board for a minute. The same is true of feeding outside. It has been a common thing for me to feed outside; and the Italians mingle together without the least trouble; but let a black bee from a neighbor's yard alight among them and he, she, or it is pounced upon instantly.

#### CAUCASIANS REAR MORE DRONES BECAUSE THE ORDINARY WORKER-CELLS ARE TOO LARGE FOR THEM.

In the June 1st issue you refer to Caucasians as great drone-producers, which seems to be a common complaint. I have had some experience with them; and while I can not say that I am an ardent admirer, yet I think we ought to "give the Devil his due," or, in other words, these bees. You know they are smaller than the ordinary bees we are accustomed to, and, as a matter of course, use smaller worker-cells for brood rearing; and when you force them on to foundation with but slightly if any smaller cells than their drone-cells, it is most natural that they should produce a large number of drones. Either give them proper foundation or let them build their own comb without interference, for then you are in a situation to judge them in this particular.

Evanston, Ill., July 15.

[The publication of that very interesting series of articles entitled "Are Bees Reflex Machines?" by Dr. von Buttel-Reepen, did not evoke the discussion that was expected. We consider this one of the most valuable contributions on practical apiculture that has ever been given: possibly the title itself led the average reader to believe that the series related to some abstruse scientific observations that were beyond the comprehension of the ordinary lay mind. This was far from the fact. The discussions are easily within the grasp of any one, and now that we have the work in book form many of our readers would do well to read it consecutively. Buttel-Reepen explains many of the phenomena that occur in the bee-yard; and these explanations will show the producer how to make more dollars out of his bees, for, understanding their nature, he is better fitted to make them serve him. Mr. Whitney, Dr. Miller, and a few others seemed to appreciate it at its real value.]

Regarding the Caucasians, we doubt very much whether they are any smaller than ordinary Italians. At one time the statement was made that the Carniolans were larger. Looks are deceiving. As a matter of fact, the three races appear to pass the zinc excluders with equal facility. We doubt, therefore, if our correspondent is right in concluding that Caucasians would build more drone comb because combs from worker foundation are too large. If we understand correctly, Caucasians in their natural habitat, on their own virgin combs, run exclusively to drones—much more so than Italians.—Ed.]

## A NEW SOURCE OF HONEY-DEW.

### A Scale Insect is Discovered in Massachusetts which Secretes a Considerable Quantity.

BY DR. BURTON N. GATES,

Bureau of Entomology, Washington, D. C.

[These observations were written for the *Journal of Economic Entomology*, Vol. II., Dec., 1909, No. 6, pages 466,467. In order to bring them before the bee-keepers, a paper has been prepared for GLEANINGS.—B. N. G.]

It is generally known that honey-dew is secreted, not alone by plant-lice or aphids, but by some scale insects, leaf-hoppers, etc. For instance, *Lecanium oleae*,\* a scale upon the citrus fruits of California, produce great quantities of honey-dew which collects as a coating upon the leaves of the trees, and is a medium for the growth of a fungus, *Capnodium sp.* The mycelium of this fungus is sometimes so luxuriant as to form a felt over its leaf, closing the stoma and thus killing the tree.

A source of considerable honey-dew, other than from plant-lice, was discovered by the author at Amherst, Massachusetts, in May and June, 1908. Large numbers of bees were observed humming through the spruce-trees on the campus of the Massachusetts Agricultural College. At times the roar was suggestive of a swarm. Closer examination also suggested that the bees were gathering propolis materials from the resinous exudations of the spruces. None, however, were seen with a burden packed upon their legs, as is the case when collecting propolis.

By following single bees it was possible to see them alight on twigs near the union of the last two years' growths, and search with outstretched tongues for something apparently sweet. At the bases of what appeared to be the dormant buds on the twigs, the bees found their sweets and set to work as vigorously as at drops of nectar. Upon crushing this bud-resembling structure they were found to be made up of animal tissue instead of plant tissue. They proved to be living insects—scale insects. There were thousands of them on the spruces from which the bees were collecting liberal stores of honey-dew. Some scales apparently produced more of the substance than others, because frequently dried crystals or globules of honey-dew were noticed at the base of the insects.

Specimens of the insects were sent to Mr. J. G. Sanders, of the Bureau of Entomology, who determined the scale to be *Physokermes piceae* Schr., "A European species which affects the spruces and only recently has been introduced into the United States." In Massachusetts it has been collected in at least three localities. The species is not likely to become a serious pest to the spruces, Mr. Sanders wrote, because of its numerous parasites; consequently, kee-keepers will

probably not be greatly annoyed with the honey-dew which it produces, as compared, for instance, with the enormous quantities from plant-lice.

Washington, D. C.

## DO BEES STEAL EGGS?

### Some Proof to Show that Eggs were Carried from Another Hive and Used for Starting Cells.

BY M. T. PRITCHARD.

On p. 781, Dec. 15, the editor asks for definite facts regarding the stealing of eggs by queenless bees with which to raise themselves a queen. In the early part of the season of 1906 we had trouble with our queenless colonies used for grafting. Nearly every day we found cells started with either eggs or young larvæ in them, resulting in the bees refusing to accept the grafted cell given to them. This we could not account for, as these colonies are not used to graft into until five or six days after they are made queenless. Occasionally one of these cells would be overlooked and a virgin hatch, each of which proved to be a *black* virgin.

All colonies in the yard were Italians with tested Italian queens except one. This was a fine imported Carniolan queen kept in a very weak colony to prevent her from rearing any drones; consequently we concluded that the queenless bees were stealing eggs from the Carniolan colony; and to test it we saved several of these cells and hatched them, and found that each one produced a typical Carniolan virgin. We then removed the Carniolan colony from the yard, and had very little trouble with natural cells from that time.

Our theory is that the Carniolan colony being light, or from some other reason, did not defend its entrance as well as the other colonies, and the queenless bees found it an easy place to steal eggs.

Medina, O., Dec. 27.

[Mr. Pritchard is the man in charge of our north yard, the one who, in fact, raised nearly 3000 queens, with the help of a boy, in a space of about four months. If robber bees can steal honey from other hives, we see no reason why a dire need of eggs should not impel bees to get the eggs from some other colony. It is altogether improbable that they would attempt to steal them from a strong colony, but, rather, find some weak nucleus, just as they did in this case. The fact that the eggs in the pure Italian colony developed into *black* queens seems almost absolute proof that the eggs in question were stolen from this Carniolan colony, and carried to this Italian colony and placed in the cells. It only illustrates how nature will sometimes take extraordinary means to prevent extinction of the individuals, or, in this case, a colony of bees.—ED.]

## HEADS OF GRAIN FROM DIFFERENT FIELDS

### SPACING DANZENBAKER FRAMES WIDER FOR EXTRACTING.

I was much interested in the question asked by Mr. Richard Hanlon, page 785, Dec. 15, and your answer to the same on the next page. I have reference to the one about spacing Danzenbaker frames for the purpose of producing extracted honey. This question is, I think, a very pertinent one to us bee-keepers who are using the Danzenbaker hive. Thus far I have never produced any extracted honey; but as I see my apiary increasing, and learn through reading the journals that extracted honey is easier to produce, that bees swarm much less—or, rather, swarming is easier controlled—and that it is as profitable withal, it brings forward very forcibly this question of extra spacing in the supers. The writer has spent many of his spare moments in trying to devise ways and means to that end. I should like to ask why The A. I. Root Co. could not, by making a slight change in the metal spacers used in spacing the Hoffman frames, give us a spacer that would be practical. The change, as I see it, would be to make the central space of such spacer wider, so it would extend clear across the top of the end-bar of said frame. Why could we not use staples in alternate sides of end-bars? I realize that there would be some disadvantages connected with such forms of spacing the Danzenbaker frame—one thing, the end-bars fitting so close to the cleats that the bees would, I think, propolize them fast to said cleats; then, again, if one wished to lift a frame of brood out of the brood-nest to the super above, which, I understand, is considered desirable, it would not work very well with the staple-spaced frame; but if the metal spacers were used it would not be so bad, and certainly would be better, on account of uncapping, than to use the frame in the super the same as it is used in the brood-nest. Then there is another thing: I suspect the bees would work to the disadvantage of the bee-keeper if these frames were spaced as I have intimated above; and that is, to build comb clear around the edges of the end-bars and attach it to the body of the hive.

Robbinsville, N. J., Dec. 27.

J. L. HOWE.

[While it would be possible to space closed-end Danzenbaker frames wider apart by means of staples or other device, we would not recommend it. We doubt very much if the gain in thicker comb would compensate for the extra expense and annoyance in handling these closed-end frames with additional spacers. On the other hand, Hoffman frames can be spaced so that eight of them, or even six, will fill a ten-frame hive-body. The advantage of spacing such frames wide apart lies in the fact that extra thickness of comb will reach out to or beyond the width of the widened ends, thus clearing the uncapping-knife. Notwithstanding this, however, the majority use Hoffman frames, for extracting, spaced in the regular way, placing all the frames in contact with each other. If this is true, there is no reason why the user of Danzenbaker frames may not do the same thing.—ED.]

### GIVING AWAY BUCKWHEAT SEED.

You mention the fact of giving farmers buckwheat as seed, in the interest of your bees, as fall honey bloom. Will you please tell me how much seed they sowed to the acre? also, with you, what per acre generally has been their return? Is there inducement enough to stimulate them to continue? At what price can it be had at Medina? Does it yield a nectar that sells well on the market? Any information you can give me will be appreciated.

M. F. SOULE.

Crestline, O., Dec. 29.

[The amount of buckwheat to sow per acre depends somewhat on the time of the year, the kind of land, and probably something upon the locality. In and about Medina we sow, on rich land for early sowing, one peck per acre; on poor thin land, two or three pecks; as late as Aug. 1, four pecks might be required. A five-peck seeding as early as July 15, on any good land, is inclined to run too much to stalk, to lodge, fall down, and amount to nothing. This lodging may be corrected somewhat by the use of commercial fertilizer.

Our experiments during the past summer in growing a considerable acreage of buckwheat in the vicinity of our north yard was indecisive as to the amount

of honey gathered. Our bees flew often enough to the fields, but the yield of honey apparently was not as large as from the crop that was sown on May 15 near our home yard. This made a splendid growth, and the bees were very busy on it nights and mornings. Contrary to what we expected, we harvested a good crop of seed. The conditions of weather for this early sowing were exceedingly favorable that year.

As to the amount of buckwheat that can be secured per acre, that depends upon the land and the kind of season. We have harvested as high as 45 bushels per acre. While this was good for Ohio, it would be considered a moderate yield for Northern Michigan, Wisconsin, Canada, or New York.

We would generally advise sowing right after plowing up wheat stubble. In this way we get two crops off the same land.

The honey from buckwheat is dark-colored, and a good many people regard it as the finest of all honeys for eating. Some who were brought up in the buckwheat sections of New York highly prize this dark honey, preferring it to the best clover, basswood, alfalfa, or sage. The average consumer, however, does not care much for it.

Buckwheat brings in Medina at the present time about 70 cts. per bushel.

Fuller particulars on buckwheat-growing may be found by referring to pages 317, 347, of last year's volume of GLEANINGS.—ED.]

### CANDIED EXTRACTED HONEY AS A WINTER FOOD FOR BEES.

Kindly allow me to make a correction. On page 772, Dec. 15, I state, "On this account we have adopted the plan of feeding between March 1st and 15th," etc. This should read "between March 1st and May 15th." On p. 786 of the same issue I find the heading, "Candied Honey for Winter Food." I tried candied extracted, but do not like to use candied honey in the combs. I have, however, used a great deal of candied extracted honey, feeding it in the months of December and January. I used several hundred pounds in the winter of 1908, and also some this winter. I place a shallow super or extracting-box on top of the hive, lay a board across the frames, place thereon ten to twenty pounds of granulated honey, and cover with a piece of burlap. The bees so fed come out in good condition.

This might be a failure in a severely cold climate. The winters here are open, sunshine nearly day, enabling the bees to fly every day with very few exceptions.

Hagerman, N. M., Dec. 27.

H. C. BARRON.

### NO GNAWING WHEN HALF-SPLINTS ARE USED.

I find that, when splints are boiled a few minutes only, the bees will gnaw them; but when they are boiled an hour the wood becomes saturated with wax so that the bees do not seem inclined to gnaw.

I used many splints last season, and have tried both ways; but I find that, when they are boiled a long time, the bees do not bother them. I use only half-splints, because when I let the splints extend down to the bottom-bar the bees gnaw the two lower inches, so I tried cutting the splints in two in the middle, and have had no trouble since. H. E. Crowther uses only half-splints, and I have never found any gnawing in his yard.

I take a bunch of 500 splints and tie a string around each end, and cut it in two in the middle and drop each half bunch into boiling wax. Any number of splints may be boiled in this way, and those not needed may be laid away to be used at another time, when it is necessary to drop them into boiling wax for a few minutes only.

GEO. E. COFFIN.

Parma, Idaho, Nov. 22.

### TROPICAL GRASSES FOR SPLINTS.

I notice that some substitute for splints is wanted that the bees can not gnaw. Such a substitute could be found in some of the grasses growing in the East Indies. I have not seen them grow, but I have seen broom-grasses bought in Singapore that I am sure would be the very thing. The color is brown, and they are very stiff. They are used for scrubbing decks.

STEPHEN ANTHONY.

Waitete, Auckland, New Zealand, Nov. 8.

### MOVING BEES IN MID-WINTER.

I moved a load of bees on a sleigh last winter in February a distance of five miles, and I never had bees come out of the cellar in the spring in better shape.

Haskinville, N. Y.

M. C. SILSBEE.

# OUR HOMES

BY A. I. ROOT.

Thou shalt not covet.—EXODUS 20: 17.

There are good people in this world—a lot of them—people who, we might almost say, never do any thing that they *know* to be wrong. I often think myself that I do not feel that I want any thing that belongs to somebody else. A stalwart friend of mine, and a hard-working man, once said to me, "Mr. Root, I do not want a copper that I have not honestly earned;" and I think he told the truth. I replied, "Neither do I want a copper that I have not honestly earned."

Well, this friend went on to say that this text at the head of my talk was all right; but when it came to keeping that commandment he thought it was a rather tough matter. He was an earnest Christian man too. I quote his language as nearly as I can remember: "Paul tells us about a thorn he had in his flesh. Well, do you know, Mr. Root, I have been having a thorn in my flesh? It follows me like a low-lived dog; and, no matter how much I kick and abuse that dog, and shake him off, he seems soon to catch up, and to be pushing his nose into my affairs, getting his head between my feet, and sometimes he almost pesters the life out of me. But the Lord said, 'My grace is sufficient for thee,' and I have found it so."

That stalwart Christian man then related to me an incident of that low-lived dog which is worth repeating here. He said:

"It occurred right in church on God's holy day, surrounded by good Christian people; and, besides that, I was sitting close up beside my pastor, whom I loved and admired. Before he commenced his lesson he explained that our Sunday-school was going to make an appeal for money for a special cause, and he very much desired that his Bible class should set a good example. So saying he put his hand into his pocket and took out a quarter. I also took out a quarter. He asked the man who was taking up the collection to hurry up as we were already late in getting started. Now, the quarter I had in my hand was bogus, and I knew it. As my fingers slipped over the smooth coin it awakened old recollections, and I could not think at first what it was that conscience was prodding me about. As the collector came along he put out his hand for my contribution, and I recollected that the coin was bogus. As quick as lightning, that dog I have been telling you about, that had followed me all my life, suggested that the coin was innocently received by me, and it was not my business to lose it. For a moment I meditated putting the coin back into my pocket and getting something else for my contribution; but this dog or devil was suggesting that I was hindering matters—to 'let it slide,' and I did."

I started this Home paper with the expectation of saying something about making and passing counterfeit money. Somehow or other the above incident makes me feel as if there were a good many of us who have

dogs following us; but "my grace is sufficient for thee."

Why should *anybody* be willing to have any thing to do with counterfeit money? Where a man deliberately sends, say, \$2.50 of good money for \$25.00 that is counterfeit, and in return gets a box of sawdust, we say it is good enough for him. Every little while our United States detectives are getting hold of counterfeiters; and a good deal of the time they find *women* assisting in the work. We can imagine a man who wants money he has not earned; but the whole wide world naturally expects something better of women. I believe that counterfeiters excuse themselves by saying that Uncle Sam is so rich he will not mind it and never know it. What kind of philosophy is that? If the world could be cured of the sin of covetousness there would be no stealing—certainly no highway robbery. What an awful picture of total depravity comes up before us when we read of a highwayman knocking a man down and pounding him into unconsciousness in order to get his watch and money! This wretch in human form pounds and mutilates a poor hard-working man just as he would pound or mutilate somebody who had wronged him or injured him in some way. When a murder is committed, a great many times the criminal tries to maintain that he did it in self-defense—he had no choice but to kill or be killed. But this hold-up fellow or fellows have no such claim at all. They waylay an innocent honest person who is guilty of no offense unless it is that of being in a lonely place at a late hour of the night. Oftentimes a day laborer is waylaid, and may be crippled for life, if not killed outright, just to get hold of his meager earnings; and of late, *women* have been knocked down and choked in order to stop their screams, that these wretches might get hold of their pitiful earnings. Of course the saloon and the drink habit are at the bottom of most of this business. Every little while forgeries are unearthed, and cases of systematic stealing that had been going on sometimes for years. All of these terrible crimes are the outcropping and culmination of breaking that one commandment, "Thou shalt not covet."

We are often told that prevention is better than cure, and that the remedy for these crimes—at least the most sensible remedy—would be to commence away back. Teach the little children to have a *sacred regard* for what belongs to somebody else. Explain to them how wicked it is in God's sight even to *desire* what belongs to another. Teach them that a coin found on the sidewalk is not their own—at least until they have made every possible effort to find out who dropped it and to whom it justly belongs; and teach them, above all things, to respect the money and property that belong to the great public. Why is it that we constantly hear of so many people who, without conscience or scruple, appropriate public money? Our hard-working people are taxed; and, thank God, they are beginning to wake up and inquire *why* and for *what purpose* they are being taxed.

Those who live in growing towns and cities have grievous burdens thrust upon them; and yet public officers—men who have been considered straight and square when they are put into office (and have an opportunity) if they discover that nobody is watching them, because, perhaps, the people have unlimited confidence in their integrity—when they discover, as I have said, that nobody is watching, what a shame and disgrace it is—yes, a disgrace on humanity—that they *too* have been helping themselves instead of fulfilling their oath of office, and protecting the people who elected them! May God help us to bring about a reform and a revival along this very line. May that old tenth commandment—the one winding up the whole list—be held up and glorified by all the world as it has never been held up before—“Thou shalt not covet.”

David was a man after God's own heart, we are told; and he was so in his youth, and even until he had got to be pretty well along in life—a man whose life and character pleased God—that is, when compared with the other people in that early period of the world's history. In the 11th chapter of II. Samuel we read, “The Lord sent Nathan unto David.” Nathan came and told David the king a little story. I suppose the king understood it was something that recently happened in his domain. There were two men. One of them was very rich, with great flocks and herds. The other was a poor man who had almost nothing, and nothing at all in the way of flocks and herds except one pet lamb which was a great favorite with all the family. Well, this rich man had a visitor, and the rich man was in a hurry to prepare a repast for his guest. But instead of drawing on his own great possessions he sent and got the poor man's pet lamb; and he probably thought that, because of his riches and power, and of his neighbor's helplessness, nothing would be done about it. When David heard of it he was so incensed that he decided, after the fashion of kings in those days, that the rich man should be put to death. This severe punishment was probably to be considered a rebuke, and establish a precedent. After the king had pronounced sentence on this greedy rich man he naturally inquired who it was that had been guilty of such a dastardly act. The old prophet then looked the king squarely in the face and said, “Thou art the man.” Oh that we had some such prophets nowadays who would not be afraid to risk their lives, and who would dare to rebuke grievous sins in that way! David had been spoiled by too much prosperity. God, in his loving kindness, had given him every thing. He had wives without number; and, human-like, he was not satisfied. He cast covetous eyes on the wife of another man—the wife of a faithful soldier and a devoted follower of the king; and because this man stood in the way of his greed he caused him to be placed where his loyalty to the king would be the cause of his own death. Oh that we had more men who could stand prosperity and promotion—who could be

true steel, no matter how much prosperity and every thing else might be entrusted to their care! May God help us as a people and as a nation.

## POULTRY DEPARTMENT

BY A. I. ROOT.

---

---

### CHICKENS IN FLORIDA—MORE ABOUT IT.

When the 60 chicks in that “basket brooder” were, the oldest of them, about two weeks old, their quarters were getting small for them; and as I had in readiness a Clough lampless brooder that I have already mentioned I moved them over on to my newly purchased and fenced acre. This brooder costs \$5.00; and the “runway,” which is a sort of protected dooryard, is \$2.50 more. Well, I sent for the runway *particularly*, to have them secure from prowlers, even if the front door of the brooder was left wide open nights for ventilation. This dooryard is protected on top with  $\frac{3}{4}$ -inch-mesh wire netting; and as it is to be placed in front of the brooder right close down on solid ground, the chicks are supposed to be safe. It *did* occur to me that I had heard of animals digging under the edges of the coop or brooder; but as the directions said nothing about further protection I concluded it was safe. The circular declares repeatedly that the complete \$7.50 combination is “animal proof;” and the word *animal*, to add emphasis, is in capital letters. Why am I all the while buying *more* brooders, especially when my own ten-cent one is *such* a good one? Well, because I want to get fully *posted* while I am about it. Did you ever have a bunch of chickens that pleased you so much every time you looked at them that you almost feared some calamity *would* befall them? Well, it was only yesterday when I saw those first 28 (that came from the Cyphers incubator) go on exploring expeditions over a great part of their new acre that I said to myself, “How I shall enjoy seeing these lusty fellows grow to big fowls before I go back to Ohio in May!” and then I added in thought, “Surely nothing can happen to *all* of them at any rate;” and then as they came tearing back, some on the wing, I added, “Did anybody ever see such large gauzy wings before, on chickens only fourteen days old?” Well, listen! this morning when I went out to see my pets, before it was quite daylight, I found one sprawled out dead in front of the entrance. I tore off the hover, and the greater part of my flock lay dead and wounded, scattered all over the floor. Just a few were moving a little, and making pitiful peeps of distress. Investigation showed that some animal had dug under the edge of this “animal-proof” runway, and then just “slaughtered the innocents.” Five or ten cents' worth of this same  $\frac{3}{4}$ -inch netting on the bottom as well

as the top would have saved *me* several dollars' worth of agony.

Let me digress a little. Of late years I find myself getting more and more forgetful. Several times I have gone to the postoffice with important mail and forgot to mail it. I took all the mail out of my box, of course; but again and again I forgot all about the letters tucked away in my inside coat pocket. Finally, one day after I had forgotten to mail some of Mrs. Root's letters I stood up straight, threw back my shoulders, and made a "declaration" (or "declamation") something as follows: "Look here, Sue. This business of forgetting to mail letters has got to be *stopped*. We positively *will not* have any more of it." I think I smiled when I "spoke my piece;" but I was mightily *in earnest*, and I haven't once omitted to put all my mail in the office since. You *can*, my friend, remember important things if you *care enough about it*. If you are undertaking too many things for an old man or woman, then have fewer cares and worries, or carry a memorandum.

Let us get back to the chickens. I for one am done getting chickens up to two weeks old and then letting some *animal* undo all my work in just a few minutes. Poultry-netting is cheap, and it takes only a little time to make the little pets absolutely safe. You ought to be ashamed of yourself; and I for one *am* heartily ashamed of myself. I think I know now that "varmints," at least sometimes, "dig under."

As I write, Wesley is now going clear around our whole two acres, making the inch netting tight down into the ground, and then banking up along the fence besides. We are going to make frequent examinations to see if any prowler has even tried to get in; and, besides this, the chicks are going to be well "barricaded" nights, you may be sure. Wesley thinks we must have fenced in some animal when we enclosed the new acre, and it became so famished was why it killed twenty or thirty chickens when it couldn't eat more than three or four.

*One day later.*—We set a steel trap and caught him, but he dragged it into the door of the brooder and pulled himself out. He was probably a possum. He not only sorted out the largest and oldest, but, as nearly as I can make out, frightened a lot more to death, for I could discover no injury to their bodies. I say "frightened," because Wesley can't run the new lawn-mower anywhere near the chicks because they go almost crazy with fright. We have found this morning where the animal "dug under" the wire-netting fence also, and got into our enclosure, but we are still on his trail.

#### MORE TROUBLE.

After the loss, the remnant were put back into their old basket; but a shower coming up they were carried in. As we can't well feed them in the basket, when it let up a little I carried them out to the brooder again; and as it began to rain more I hastily dumped them into the yard before the entrance, the way we have a swarm of bees, for in-

stance; but the sight of the place (and the memory of the night before) seemed to frighten them so much they scattered in every direction out in the rain. Just at this crisis the rain became a regular downpour. Did you ever try catching chickens while holding an umbrella? I got them in the best I could; but both chicks and myself got a regular soaking, and then the wind swung round to the north and gave us a whiff of your Ohio zero weather just after Christmas.

Well, we have 23 sad-looking chicks left out of our beautiful flock of over 60. It almost makes me think a brooder-house would sometimes be a good thing, even down here in Southern Florida. I have raised chickens, however, down here all winter long for the past three winters, and have had almost no losses at all until just now. Had I stuck to my basket brooder, making another just like the first, when they became too crowded I might have had every chicken even yet. It seems they have got on to pretty nearly the same thing away out in California. Read the following from L. E. Keyser, in the *Petaluma Weekly* of Dec. 15:

During severe weather I kept these brooders in a hen-house having an open front, and in mild weather set them out in the yard during the day and carried them back into the house at night. This was a good deal of hard work—a thing we are trying to avoid. These brooders were light, being made out of cracker-boxes, and had handles for carrying them by. I never had chicks do better.

This is another striking illustration of how "great minds run in parallel channels;" but why in the world, brother, didn't you take light baskets instead of "cracker-boxes"?

By the way, my experience so far is in favor of a simple burlap sheet over the chicks instead of the ungainly and expensive hovers of woolen "carpet rags" hanging down over the chicks. Philo and Curtiss Bros. both seem to have adopted the burlap sheet. If the weather is very cold it is an easy matter to drop a piece of flannel over the frame holding the burlap. With the 60 in one basket they got too warm, if any thing, whatever was laid over the burlap sheet, even nights when it was down to 40.

I said in a former article the grain for 85 full-grown fowls cost only about 20 cts. a day. Since they are laying more heavily it comes to nearer 30 cts. per day; so we must have at least 9 eggs each day to pay the grain bill. Eggs are still 40 cts. per dozen.

#### MORE "TROUBLES."

Our efforts to trap the possum resulted in catching him twice; but he pulled out of the best steel trap that could be found in the neighborhood. The last time, he left in the jaws of the trap a piece of his hide, fur and all, almost as big as a half-dollar. Since then he kept away. Wesley suggests that he is finally "convinced." Well, after the possum's visit and the rainstorm's final effects were all over I had 15 chickens left that were getting so strong and well they were exploring again all over the premises. I told Mrs. Root last evening they were now all right, and even the weakest ones wouldn't need any more "hot brick," etc. Their basket

brooder was brought in every night, and placed up on a high work-bench in the woodshed, doors all closed, of course. Well, this morning, although the basket looked all right on the outside, I found six more mutilated chickens and two more missing entirely; and now we have only seven left of that beautiful flock of over 70\*. I have written two editorials about rats during the past year, and I notice Ernest has another one in our last issue, and yet I have been so stupid as to allow rats to get the most of my poor remnant of chickens. It seems I have abundant use, of late, for my little prayer, "Lord, help me to learn the lessons thou art trying to teach me." Since I seem called to hunt up and trace out the hindrances to successful poultry culture I will try to learn by experience, and thank God the experience is sent to me rather than to some one who is less able to bear it. Mrs. Root suggests that my method of feeding invites rats and other vermin to our premises, and thinks we shall have to stop leaving grain all the time right before the fowls. I have been using all summer (in Ohio) a patented feeder and exerciser, warranted to head off rats, English sparrows, and every thing else. It worked all right for a while; but the sparrows soon learned to come in droves and get right down among the fowls, and grab every grain of wheat the chickens rattled down until they were satisfied; then the chickens could get their fill. I don't see why rats might not do the same. At present a cheap tin can, something like an extractor-can, tall enough so no rat can jump in and out, seems to be the only remedy; but in this case some of the hens seem slow to learn where to go for feed, and thus go hungry. After this you may be sure all my small chickens will be kept nights in a box covered with inch poultry-netting. We are just now making a "rat-proof" brooder house 8x14 feet. This will be so made that it can be all closed up frosty mornings, letting the sunshine in through windows on the south side. We do have a little frost here sometimes. Two nights during the past week the water froze in a pail out by the pump so it took quite a little push with the finger to break it. This is, however, the coldest weather here for many years—Wesley thinks the coldest since the great freeze of 1895.

\* Just think of it (if you have had no similar experience), buying baby-chick food, boiled eggs, and meat from the butcher's, in order to have them "just get up and dust," and then when almost three weeks old, and just fairly past the critical time in a chick's life, to have some greedy "varmint" not only eat up the best of them but kill and wound a great lot he could not eat and had no use for! Never mind; it's a pretty bitter "skule," but we are learning.

I have been reading GLEANINGS for a few years, and it is packed full of good things from cover to cover. I inclose a clipping that I thought you would like to place before your readers.

Goffstown, N. H., Dec. 8.

G. W. SANDERS.

WHO ARE THE GUILTY ONES?

"Prisoner at the bar," said the judge, "have you any thing to say why sentence of death should not be passed upon you?"

A solemn hush fell over the crowded court-room, and every person waited in almost breathless expectation for the answer to that question.

The judge waited in dignified silence. Not a whisper was heard anywhere, and the situation became painfully oppressive.

Then the prisoner was seen to move. His head was raised, his hands clinched, while the blood rushed to his pale, care-worn face. Suddenly he arose to his feet, and in a low but firm voice said:

"I have, your honor. You have asked me a question; and I now ask, as a last favor on earth, that you will not interrupt my answer until I am through.

"I stand before this bar, convicted of the willful murder of my wife. Truthful witnesses have testified to the fact that I was a loafer, a drunkard, and a wretch; that I returned from one of my prolonged debauches and fired the fatal shot which killed the wife I had sworn to love, cherish, and protect.

"While I have no remembrance of committing the fatal deed, I have no right to complain nor to condemn the verdict of the twelve good men who have acted as jury in this case, for their verdict is in accordance with the evidence which I have heard.

"But, may it please the court, I wish to show that I am not alone responsible for the murder of my wife."

This startling statement created a tremendous sensation. The judge leaned over the desk, the lawyers wheeled around and faced the prisoner, while the jurors looked at each other in amazement.

The prisoner paused a moment, and then continued in the same distinct voice:

"Yes, I repeat it. I am not the only one guilty of the murder of my wife. The judge on this bench, the jury in the box, the lawyers within this bar, and most of the witnesses, including the pastor of the old church, are also guilty, before Almighty God, and will have to stand with me before his judgment throne, where we shall all be righteously judged for all our thoughts, words, and deeds.

"If there had not been saloons in my town I should not have become a drunkard, my wife would not have been murdered, and I should not be here now, ready to be hurled into eternity. Had it not been for these human traps I should have been a sober man, an industrious workman, a tender father, and a loving husband. But to-day my home is destroyed, my little children cast out on to the world, while I am to be hanged by the strong arm of the state.

"God knows I have tried to reform, and prayed for strength to withstand the licensed temptation; but so long as the open saloon was in my pathway my weak and diseased will power was no match against the fearful, agonizing, consuming appetite for drink.

"For one year our town was without a saloon. I was one of those who signed the remonstrance against the reopening of saloons in our town. One-half of this jury, the prosecuting attorney on this case, and the judge who sits on this bench, all voted for the saloons. By their votes and influence saloons were reopened, and they have helped to make me what I am."

The impassioned words of the prisoner fell like coals of fire upon the hearts of those present. The judge made a motion as if to stop further speech; but the prisoner hastily said, "Your honor, I am nearly through. Do not close my lips." Then he resumed:

"I began my downward career at a saloon bar, licensed and protected by the voters of this town. Had it not been for the license voters, the saloons which have wrecked my life and destroyed my home would not have existed. After the saloons you have established have made me a drunkard and a murderer I am taken before another bar, the bar of justice, and now the law power will conduct me to the place of execution, and hasten my soul into eternity. I shall appear before another bar then—the judgment-bar of God.

"And there you who have licensed the traffic will appear with me. Think you that the great judge will hold me, the poor weak victim of your saloons, alone responsible for the murder of my wife? Nay! I, in my drunken, frenzied, irresponsible condition, have murdered one; but you have deliberately voted for the saloons which have murdered thousands; and these saloons are in full operation to-day with your consent.

"You licensed the saloons which made me a murderer. I am the logical product of your own votes, and you are guilty with me, before God and man, for the murder of my wife.

"I stand here to-day a condemned murderer, only one of a million, the product of licensed-saloon votes. Let your conscience condemn you who have voted for the rum-shops. There is a remedy, and every sensible man knows what it is. I am done, your honor. You will close by asking God's mercy on my soul. I close by asking the Lord to have mercy on his people, and to open their blind eyes that they may cease to give their votes to consent to the running of licensed murder-mills in our country."

# GLEANINGS IN BEE CULTURE

NO. 4

## EDITORIAL

By E. R. ROOT.

OUR readers will be interested in quite a valuable communication in this issue, p. 124, from Raleigh Thompson, furnishing indisputable proof showing how bees are guided sometimes by scent to new pastures.

“ON TO HIS JOB.”

THE picture of Geo. S. Demuth, foul brood inspector for Indiana, on p. 112, indicates a remarkably pleasant face. If it is a true index of his general character (and we believe it is), he makes an ideal inspector, because he has all kinds of people to handle. Mr. Poulder's interesting article shows that he, Mr. Demuth, is “on to his job.”

THE COVER DESIGN.

ITALIAN bees are doubtless the native *Apis* of the peninsula of Italy. Roman writers made mention of bees and honey from the very earliest times, and it is reasonable to suppose that these were of the same variety as the Italian bee of to-day. The Romans attributed long life to the use of honey as one of their chief foods. The design on the cover shows an early Roman bee keeper preparing to hive a swarm.

THE HEAVY SNOWS AND CLOVER.

THE heavy amount of snow that seems to cover almost the entire northern States has spread a protecting mantle over the young clovers of last fall. This will mean much to their growth this coming summer. In this connection, it is pleasant to recollect that we have generally had a good flow from clover following a winter in which snow covered the ground almost the entire period of cold weather.

DOES ALSIKE OR WHITE CLOVER CAUSE BLOATING IN CATTLE?

SOME days ago a correspondent wrote us asking this question; and as we were not able to give authentic information we referred the matter to our Ohio Agricultural Experiment Station at Wooster, Ohio. L. H. Goddard, the chief of the department of co-operative experiments, replies:

Your letter of the 22d, regarding alsike or white clover causing bloating in cattle, is received. Reply-

ing thereto, I would say that, when cattle eat heavily of any succulent crop, such as the clovers or rape, they are subject to bloating. I do not call to mind any special experience with alsike clover, but have had quite a little experience with the ordinary medium red clover. Quite a number of cattle are lost every year from this trouble in the cattle-pasturing areas of Southwestern Ohio. By watching the herd, using a proper admixture of dry feed, and in rare cases the trocar and cannula, the most of the loss can be avoided.

L. H. GODDARD.

Wooster, Ohio, Jan. 25.

If any of our subscribers are able to give any information further than the above we shall be pleased to hear from them. So far we have had no report of white clover causing any bloating, and we doubt somewhat whether it would do it owing to the fact that cattle would not be able to get enough of it at any one time.

THE AUTOMOBILE VS. THE HORSE FOR OUT-APIARY WORK.

VERY soon we shall have several articles on automobiles for out apiary work. The time has arrived when one can buy a good serviceable machine for about the price of a good horse and buggy or horse and wagon. A machine will make trips to outyards in one-fourth the time it would take a horse, and will be capable of carrying loads up to 500 pounds. Of course, there are auto trucks that will carry two or three tons, but they cost several times more than a horse and wagon.

We have no ax to grind, no agency; and as we have had considerable experience ourselves in handling machines we can perhaps give the reader some hints on how to purchase and how to handle a machine after he gets it. This we shall do in a series of short articles.

The time is coming, if it is not already here, when the automobile will enable the bee-keeper to carry out more easily W. Z. Hutchinson's injunction to “keep more bees,” that is to say, he can have more outyards, and, what is more, spread them further apart, thus securing a wider acreage of bloom. With the machine he can go to an outyard twenty miles away in the time it would take him to go to a yard five miles away with a horse and buggy; and, what is more, the self-propelled wagon is not afraid of stings. It can be driven right among the bees, gentle or cross, and be loaded at the most convenient point without danger of a general spill or mix-up.

For the reader's present information we would advise him not to buy some new make simply because the price is low. There are several standard makes that have been on the market for years, first class in every respect, that can be bought for \$500 and under. Then if one knows how to make the selection he can purchase a number of second-hand automobiles, practically as good as new, for from \$175 to \$250. But to make the horseless carriage a success the owner must learn to be his own chauffeur: must understand something of the general principles of a gas engine, and employ a little automobile sense if not horse sense. More anon.

LOOKING BACKWARD; A. I. ROOT'S EARLY BEE-KEEPING EXPERIMENTS; THE BREAD THAT WAS CAST UPON THE WATERS COMING BACK TO-DAY.

The reader will, perhaps, be interested in the discussion between F. Dundas Todd and the editor in this issue, on page 122. No wonder Mr. Todd could find nothing in any of our current literature on the subject of giving bees meal or flour candy direct. After reading his article we recalled some of A. I. Root's early experiments away back in the 70's—how he tested this and that kind of candy; how he mixed flour and meal of various sorts into the candy; how he "scorched" his syrup and killed his bees. The result of all these experiments was given in this journal at the time. All this took place when the present editor, though a lad, was learning his A B C's.

A. I. Root, during the early 70's, could think of nothing but bees. His business of manufacturing jewelry had reached such proportions that he found it necessary to seek rest and recreation outdoors. Well do we remember how, as a boy, we went to Cleveland with him to look up books on bees; how we followed him on bee hunting expeditions; on tramps across the fields to see what the bees were working on.

Langstroth paid him a number of visits at Medina, and well do we recall the interesting chats A. I. Root had with that father of American bee keeping. Langstroth was a charming conversationalist, and we could have sat at the feet of this Gamaliel hour after hour. We have wondered many times since what it would be worth to-day if we could have had these talks taken down in shorthand, because Langstroth drew on his rich and varied experience in bee culture when he was developing and perfecting the hive and system that revolutionized bee culture throughout the world.

Then there used to come to our home such men as Dr. C. C. Miller, Mr. G. M. Doolittle, Prof. A. J. Cook, and other celebrities. At the table, almost the entire conversation was bees—bees for breakfast, bees for dinner, bees for supper, bees everywhere and all the time except when A. I. Root was attending to the jewelry business up town; but his heart was elsewhere.

He took nothing for granted, but tested

every thing in the yard. No wonder his advice was eagerly sought, because during the few years that he gave a large part of his time to his bees he exploited almost every new field.

He made the first perfect honey-extractor that had ever been sold. You should have seen the first machine. It was a rare combination of a tin can, wooden cross-arms, and an old apple-paring machine for gearwork. Later was developed the beautiful all-metal Novice extractor of to day.

He was one of the first to see that Langstroth had blazed the way for the entire world. He adopted the Langstroth hive and dimensions after having tested every form of frame and hive. He was the first to bring out the one-pound section honey-box. He tried indoor and outdoor wintering. One winter he covered every hive with a big pile of manure. It was not altogether a success. Another winter he packed the hives with straw; later on he began to follow J. H. Townley, of chaff-hive fame.

Along in the early days news came across the water of the invention of comb foundation. A. I. Root was convinced that this was a great step forward. He could hardly eat or sleep, so eager was he to get up a machine by which he could make what we then called "artificial foundations." He employed Alva A. Washburn, an expert machinist, to make him dies. In the mean time Mr. Root tried flat plates, small ones at first, and then larger ones. He had type faces made, and began the work of setting up the type and locking it up in forms. He tested every scheme then known of making comb foundation. He was the first to make foundation with a paper midrib. Later he tried thin veneer wood, and, last of all, wire. Mr. Washburn finally brought out an embossed pair of rolls that were almost as perfect as those made to-day.

It was during this period that A. I. Root built a double-walled bee-house, walls 12 inches thick, filled with sawdust. During the summer he used this for extracting, and during cold weather for wintering bees. But his indoor scheme was not altogether a success. When he adopted the J. H. Townley method of wintering in chaff he adopted what is in use to day, so successful all over the United States.

As we go back to those early days we think of the long series of experiments conducted by A. I. Root in trying to winter bees in a greenhouse. His plan was to "educate" his pets to fly out inside the greenhouse and go back into the hive. He put out rye meal, and partially succeeded in getting the bees to take it and return to the hives; but hundreds, yes, thousands of them, bumped their heads against the glass in the vain effort to escape, and the majority of them never returned. But he did succeed to some extent in getting them to visit the flowers that he had out, and go back to the hives.

We also recall how, in these early days, he tried wintering in a house-apiary. He con-

structed a double-walled hexagonal building that we still have; then put a stove inside of the building. The bees all had access to outdoors, and, theoretically, the scheme looked as if it might be a brilliant success. The stove would keep the inner room warm, and also the colonies; but the experiment, like some others, was not altogether a success. The bees were over-stimulated, and he finally came to the conclusion that artificial heat was worse than nothing.

The manufacturing jewelry-shop during that time was being converted over into a wood-working shop upstairs. First a foot-power saw was put in operation; later a power saw was attached to a windmill; and many and many a time did the writer turn in and help while A. I. Root made bee-hives. During part of this time, at least, he was writing for the *American Bee Journal* under the *nom de plume* of "Novice." These articles in both periodicals not only stimulated a demand for a full account of his experiments, but led to a call for bee-supplies. A modest little catalog was gotten out in 1873 and '4, advertising the "Simplicity" bee-hive, "Simplicity" bee feeder, "Novice" all-metal honey-extractor, metal-cornered frames, "artificial comb foundations," and dovetailed one-pound section boxes. But the demand for bee-supplies grew at such a pace that the unreliable windmill failed to keep up with the orders, and a steam-engine was put into commission. It was not long before the little shop was running night and day. Larger quarters were urgently needed, and it was plain to be seen that the jewelry business up town must be sold and a new factory put up near the railroad track. But the new building, 40x100, two story and a basement, took so much capital that it was rumored that A. I. Root would be "busted" before the year was out: that he had "bit off more than he could chew;" and it was, indeed, a serious problem as to whether he would be able to make ends meet. But his honesty, a big asset in his favor, had never been questioned; money came to his rescue from unexpected sources, and you know the sequel.

Most of this early experience that laid the foundation for his manufacturing interests, GLEANINGS IN BEE CULTURE of to-day, and the A B C and X Y Z of Bee Culture, occurred during the early 70's. Indeed, we may say that A. I. Root's best work occurred between the years 1870 and 1880. It would take a volume to record all his experiments. It is needless to say that many of them resulted in failure, and the world knows that many of them were successful. This early work cost him thousands of dollars, but the money was well invested. Fortunately for the writer and GLEANINGS IN BEE CULTURE, as well as the A B C, we were an eye-witness to practically all of this early experimental work. To have seen it, to have been in and around it, to have had knowledge of the failures as well as of his successes, is a heritage of which we feel indeed proud. While we were only a lad then, it can never be forgotten. It could not be otherwise, for A. I.

Root's enthusiasm knew no bounds. Many a time have we seen him throw up his hat in the air from the very exuberance of his enthusiasm, especially when some experiment "panned out" well. Nothing would do but that every member of the family would have to go out into the yard and see. He was a regular hobby-rider when he got started, and sometimes his friends said of him that the hobbies ran away with him.

Many and many a time when answering questions to-day we have used the knowledge of this early experimental work of A. I. Root's, some of it over thirty five years ago. For example, a correspondent had just patented a foundation having paper for a midrib. He was very enthusiastic about it, and thought it was going to work a revolution. Remembering well that A. I. Root had been all over this, that bees many times would reject the foundation with a paper midrib, we felt it our duty to tell our correspondent the plain truth, and we did. At another time our friend Danzenbaker got up a valveless smoker, and even went so far as to patent it. Going back in memory we recalled the time when A. I. Root made just such a smoker, and how he sold them by the thousand. Then when Mr. Todd desired to know something about giving bees nitrogenous food in the hive, those early experiments came back to mind again, and a reference to the back volumes of GLEANINGS soon brought the whole thing back vividly as if it were yesterday. These are only samples from the storehouse of those early days, and GLEANINGS is profiting by it even to-day.

*Later.*—A proof of this was sent to A. I. Root for suggestions or corrections. In reference to the feeding of rye meal in the greenhouse he says:

Just a word in regard to the feeding rye flour in the greenhouse, alluded to in the above. At that time I was losing many colonies by "spring dwindling," and sometimes these contained valuable queens that it was quite an object to save. I figured this way: If I could construct a greenhouse that would enable me, with protection, to feed up a weak colony and get it to rearing young bees under glass, there need be no spring losses. Well, I succeeded in feeding the bees under glass, getting them to fly from the feeder back to their hive safely and *build comb*; but, although the queen laid eggs every day, none of the eggs were ever hatched into larvæ. Something was evidently wanting, and at this crisis I got them to working on rye meal as well as the syrup. When the first bee loaded up with pollen, and flew safely back into the hive, I sailed my cap. Next morning the eggs were swimming in the well-known milky food, and in three days or less we had a patch of larvæ growing as naturally in the month of January under glass as we usually see it in May. I declared then I was "out of the woods," and henceforth there need be no more "spring dwindling." Mrs. Root, however, suggested it was unwise to "count chickens," etc. Well, after I had a lot of young bees not only hatched under glass, but out in the sun, trying their wings and having their natural "playpell," then I called all the family to witness that my "gold-mine" was a reality. I did build up several weak colonies in this way and saved them; but it was a lot of work, and when a warm day came and the greenhouse had to be opened for ventilation, the bees got out and didn't find their way back. We put wire cloth over the ventilators, but the bees buzzed on the wire cloth, and many were lost. There are now bees kept regularly in the large cucumber-greenhouse to fertilize the blossoms. When one colony gets weak from loss of bees another is moved in while the first is put out to build up again. I at least fully demonstrated that bees can not rear brood on honey alone. They must have pollen or a substitute.—A. I. R.

## STRAY STRAWS

BY DR. C. C. MILLER, MARENGO, ILL.

ON PAGE 81, third full paragraph last line but three, should it not be "Leave 10 days" instead of "2 days?" [Yes, you are right. This was a typographical error.—ED.]

IF I UNDERSTAND, p. 81, correctly, putting a story filled with European foul brood on top of an excluder over a healthy colony will not infect the latter. Is that possible? [We would doubt the wisdom of placing healthy brood over a colony that has disease, although perhaps it can be done.—ED.]

MR. EDITOR, you have expressed page 89, what I have been quietly thinking for some time, and mustering courage to say—that whatever extra immunity to foul brood Italians may have, is not because they are Italians, but because of their extra vigor. If you get that same vigor in any other bee you will get the same immunity.

AMENDMENT to Straw, page 68. Instead of placing hives singly in a row, place them in pairs, as said on p. 68. Then to each of these pairs set another pair, the two pairs back to back. That will give you four times as many hives on the same ground as by setting hives singly, with no more danger of bees entering wrong hives in one case than the other.

GEORGE E. COFFIN, please accept thanks for that little kink of boiling a lot of splints in advance, to be laid away for another time, p. 92. Simple as it is, I wasn't smart enough to think of it. It's more troublesome to boil a few at a time as you use them. Now will some one please tell me the best temperature for the splints when being pressed into the foundation? Should they be lifted directly out of the wax boiling hot, nearly cold, or how?

I'M AFRAID, friend A. I., that when Wesley has got clear around that two acres, making the netting tight down into the ground, and banking up besides some of your biddies will still come to grief. The varmints will naturally dig down when they come to obstructions, and then work under. I'll tell you what to do: Let down the netting so that it laps over on the ground six inches outside. The varmints don't know enough to start back that far from the fence.

THE THING I always dreaded most about out-apiaries was the hauling, and I thought if I could only haul bees without horses all would be lovely. But that story of R. F. Holtermann, page 75, shows that horseless hauling has troubles too, and I'm more glad than ever that I'm down to one apiary. [Holtermann would have got along very nicely with his traction engine had it not been for the deep sand and mud. He planned all right; but no man can figure on a thunder-shower coming on at any given minute. The troubles of a traction engine in the mud are much the same as we find with an automobile. Just after a good smart shower the

roads are much more slippery than after an hour or two. Our friend Holtermann was trying to make a trip, rain or shine.—ED.]

A. I. ROOT, some of us may resist all the things you mention, p. 93, and yet tr p up on something else. For example, some people think it almost a joke if they can evade paying on a street car, not realizing that it is just as much stealing as if they took 5 cents out of some one's pocket. I've heard it defended by saying, "It's the conductor's business to collect it;" but that doesn't lessen your obligation to pay it. I knew a person who was always on the lookout for postage-stamps that had been used and not properly canceled, believing it all right to use them again, not realizing that to use such a stamp was stealing two cents.

WESLEY FOSTER, the wind may make a difference by hindering or helping flight, as you say, p. 69 but I suspect it makes vastly more difference by wafting the fragrance. Ever watch bees working on a basswood or fruit tree?—always hovering on the leeward, never on the windward side, even in a very gentle breeze which can not affect their flight. I don't know, but I should think they would work against rather than with the wind; for when working against the wind the fragrance is always toling them further on, while with the wind the fragrance is always at their backs. [This is similar to the theory that E. D. Townsend employs in his argument, page 110 of this issue. You are not talking about the same thing, of course, but your reasoning is the same. We believe you are right, too.—ED.]

ERNEST, that's a good idea, page 65, to eat your breakfast food and honey cool: but for the sake of accommodating an old friend couldn't you just as well eat it at the beginning of your breakfast and still have it cooled? Spread it out on a plate and it soon cools. I'm afraid there is something wrong about this whole dessert business. Generally it means just so much added after a full meal has been taken, and that has shortened many a life. I don't want to be lonesome, and I'd like to have you live as long as I do. [It is not the general policy at our house to have dessert after a meal. We cut that out years and years ago. But the cold breakfast food that we were talking about is not strictly a dessert. It is taken as a part of the ration that sustains the natural wear and tear of the body and mind. We have tried cooling off the breakfast food by spreading it out on a plate as you suggest. The plate soon absorbs a part of the heat, and then slowly gives it back to the breakfast food. No, we want our food either *hot* or *cold*. We want our breakfast food served *cold* either at the close or near the close of the meal if we are to have honey in it. By the way, the old-fashioned cracked wheat (we crack ours in a small hand grinder) cooked in the good old way, and served cold with thick extracted honey, beats any modern breakfast food that was ever pu on the market, and it does not cost a quarter as much.—ED.]

## BEE-KEEPING IN THE SOUTHWEST

BY LOUIS SCHOLL, NEW BRAUNFELS, TEX.

Texas prospects are fine, for the 1910 honey crop promises to be a big one.

### THE AGE OF HONEY.

Referring to my article on this subject in a former issue, Mr. R. Kuhne, of Pomona, Cal., has this to say: "You are entirely correct in what you say concerning the age of honey. I have samples of orange honey that I have kept for the last twelve years, and the color as well as the flavor is different every year. That produced ten years ago approaches a dark brown."

### OUR FIRST INSPECTION TRIP IN THE SPRING.

Every fine day that we have now we visit some one of our apiaries, many of which we have not seen since the last honey was hauled away in August or September. Our work on these trips consists in overhauling every colony, taking an inventory of the stores, seeing whether there are queens, determining the number of weak or dead colonies. Each hive has a super or two with shallow combs partly filled with honey, and these are slightly tilted up, so that a glance tells us the condition of the cluster and whether there is the right amount of honey in the brood-chambers. The weight of the supers is also noted when they are raised. If all is well the supers are put into place, and a small stone or half brick (always used on our hives to mark the conditions) is placed on the front end of the cover. If the colony has a superabundance of stores, and can spare some for others that are needy, another small stone is placed beside the one already on the front end. If the colony should be short of stores the stone is placed at the rear of the cover. Weak colonies are designated by two stones at the center of the cover, and queenless colonies by a stone at each end. When we have gone through the whole yard we are ready to equalize; and as many as have two stones on the rear of the cover, showing that they need to be fed, receive a super from those that have two stones on the front end. The light or empty super that was on the needy colony is put back on the hive from which we took the full super. On each cover, after this change is made, one stone is then placed at the front, like all the rest which are "O. K."

All weak and queenless colonies are united. We simply set the brood-chamber of each queenless colony on top of a weak queenright colony, making sure that there are enough stores. Then a stone on the front end of the cover shows that these colonies are O. K. also. If there should be only one or two weak or queenless colonies, and if it is not possible or desirable to unite

them, they are distributed around on top of some of the colonies in the yard that are not quite as strong as others.

All this requires very little time, and yet the work is thoroughly done. By keeping part of the stores in the supers left on the hives the year round, and when the cluster is nested between the brood chamber and super (the place which the bees seem to prefer), it is an easy matter to ascertain the conditions *in a moment*, and also of the stores, without prying off a single cover of the hundreds of colonies that are examined.

We make a note of the number of colonies that are finally all right for spring count, and in this way we can know the number of bottoms and covers that may be used for some increase later; also, at the same time, we make a note of other conditions that may be of interest. The number of weak colonies and the condition of all the others is generally noted down for references, while an inventory of the stock at the yard is taken, which aids materially in planning the season's work, for we can thus know what may be needed at each place. The yard is then left for our next trip a month later.

### OUR SPRING CLEANING.

February is the month when we have a regular house-cleaning in all of our yards. All the hives are leveled anew, and put on a good foundation. The hives have a fashion of leaning in all directions at the end of the season if a heavy load of honey has been stored, and especially if the soil in the yard is loose. These have to be straightened up again; new foundations for increase or other colonies are put down also. For our foundations we use broken bricks, which can usually be had for nothing. Often such heaps can be found in back yards or in out-of-the-way places. Two halves of a brick are placed under the front cleat of the bottom-board while one under the center of the back cleat is sufficient. Four bricks one at each corner, would be better in soft ground, if there are plenty of bricks. It takes a large number for a thousand colonies.

All worthless covers and bottoms are replaced by good ones, and dilapidated fixtures are taken home for repairs and made ready for use later. Everything about the yard is straightened up; the fences are repaired, and the roads leading to the apiaries are put in good shape for the season. Limbs that are in the way, and all unnecessary brush and trees, are cut down. The stove-wood is cut out of it, and the rest is burned with all the trash which can be raked up. A wonderful change is wrought in the looks of each yard, and it pays to have every thing in apple pie order and out of the way for the rush later. If the weather is warm enough, every thing receives another coat of paint also, except such hives as have been painted within the last year or so. Three or four weeks later the colonies are all overhauled for an inside cleaning.

## SIFTINGS.

By J. E. CRANE, MIDDLEBURY, VT.

That seat and tool-box, page 699, Nov. 15, looks as though it might be a fine thing where the hives are low enough. It is much better than a one-legged stool.

If a beginner can not profit by an illustrated article, page 739, Dec. 1, on handling combs that are insecurely fastened in the frames he had better give up the business.

On these cold winter mornings, as we eat honey on our buckwheat cakes we should remember the thousands of bees that spent their lives collecting the nectar that we enjoy.

Mr. Foster, page 591, Oct. 1, has some very good ideas about marketing or selling honey. "Visit with him," the prospective buyer; "any man you are talking with should be your friend—that is, you should meet on a friendly basis." This is *golden*.

We are glad that the white-clover prospects of the country are good, page 721, Dec. 1. They are not as good in this section as we wish, for our autumn was as dry as it was a year ago. We have a much better show for alsike, however, than last year.

Page 696, Nov. 15, in the discussion on hive size I found myself, after using ten-frame Langstroth for years, drop to eight frames for comb-honey production, and again when, three or four years ago, we began extracting we went back to the ten-frame size as larger.

Dr. Miller gives his experience in feeding sugar syrup, page 590, Oct. 1, and again on page 724, Dec. 1, and he comes to the conclusion that two or two and a half sugar to one of water is about right. I agree with you, doctor, on the two-to-one basis. We have fed some 8000 lbs. of sugar this fall with about 4000 lbs. of water and 800 of extracted honey.

The Massachusetts Society of Bee-keepers invited me down to Boston the first week in December to tell them how to produce honey in New England; but after hearing President Britton tell how sections should be put on as soon as honey came freely, and that he had taken off finished sections the 19th of April, and had the past season taken 300 lbs. of comb honey from a single colony, I thought I would like to go to school awhile before I tried to teach.

On p. 622, shade in the morning is represented as being detrimental to the welfare of the colony of bees. I have some doubts

in regard to this. I have kept bees for many years in places where the sun scarcely ever shone on the hives, and have failed to notice enough difference to make it worth while changing their location; indeed, I have sometimes found my most productive colonies in such places. [Let us hear from others on this.—ED.]

Dr. Miller, page 656, Nov. 1, thinks it possible that there may be a difference in honey-dew that makes bees winter on it in some places and die in others, while the editor thinks the difference not "dew" so much to the "dew" as to the honey mixed with the "dew."

Well, Mr. Editor, here is a clear case of where you and I don't think alike. Some years ago we had a great flow of honey-dew about Sept. 1, after all white honey was gathered, and we have little other in this section. I had three large apiaries stretching from east to west about three and a half miles apart. The conditions were as nearly alike as they well could be, as it seemed to me; yet the two outside yards wintered very badly while the one between them wintered with little loss. The same appeared to be true in other locations further north. Now, isn't it reasonable to suppose that the honey-dew from oaks or elms should be quite different from that gathered from basswood? We know that that from willows is of such inferior quality that even the bees refuse to gather it when abundant. [We don't know.—ED.]

I was much interested in Dr. Miller's article on the improvement of bees, page 697, Nov. 15, and especially in the fact that he thinks the black bee of Switzerland a distinct type. I believe that these bees are no better than our own, or, at least, than the better strains of our black bees, and that the reason they are so highly prized by the Swiss is that they are better adapted to the flora of Switzerland than the Italian bees. Bee-keepers living in sections where buckwheat is the principal source of honey have told me that they get better results and more honey from the blacks than from the Italians, or from a mixture of the two. I have noticed of late, however, that the Italians are being used more extensively, even in buckwheat localities, but not, so far as I have learned, because the Italians gather more honey, but because they are better able to battle with disease. May this not be the reason why some methods of treating foul brood are more successful with some bee-keepers than with others? Mr. E. W. Alexander, whose method of treatment of the black or European foul brood was by simply keeping his colonies queenless for three weeks, used the Italian bees, I think, exclusively; and Dr. Miller, in curing his bees so successfully, also has this race. Has any one with black bees tried the Alexander method? If so, what has been the success of such trial? [Dr. Miller's bees are hybrids.—ED.]

## CONVERSATIONS WITH DOOLITTLE

AT BORODINO, NEW YORK.

### DOES THE AGE OF QUEENS GOVERN SWARMING?

"Mr. Doolittle, do you think that the age of queens has any thing to do with the tendency of colonies to swarm? A bee-keeper from the East was at my house a few days ago, and he claimed that his colonies having queens only one year old were very much more inclined to swarm than those having older queens."

"I hardly think that is the case, friend Hunt; but to be sure that such a claim was right it would be necessary to know how many colonies having queens of different ages were in observation, and to know what proportion of them swarmed."

"I did not think to ask him about that. I myself think that colonies having the year-old queens are less inclined to swarm than those having two, three, or even four year old. In other words, my experience seems to indicate that the older the queens in any colonies, the more those colonies are inclined to swarm."

"Possibly you are right; but I think other conditions have a greater bearing on the swarming matter than the age of queens. Sometimes it may be one condition, sometimes another, and perhaps more than one. If there is a lack of ventilation, causing extreme heat, or any other condition which may render the hive decidedly uncomfortable, I have known bees to swarm without even beginning the construction of queen-cells."

"Well, now you speak of it I do believe this may have much to do with swarming; for one summer I had my bees in a place entirely surrounded with trees and buildings so that scarcely a breath of air could get to them, while the sun poured in on them from eight in the morning till four at night, and those colonies, while left there, swarmed to beat the band, as the expression goes."

"Again, it may be the failure of the queen to lay sufficiently. Under this condition queen-cells are built; and if the season of the year and weather conditions are all right, swarming will follow; if not, the queen will be superseded. However, more frequently it is the lack of sufficient room, or, to put it more nearly correct, lack of empty combs for the queen to lay in, that causes swarming."

"Yes, the bees begin to restrict the queen as to the number of eggs she lays, as I have sometimes expressed myself. There is a whole lot to this swarming question."

"Now let us come a little closer home in this matter. We are comb-honey producers, therefore we can look into that part of the matter. We can give room enough in the supers, but this is mostly in the shape of foundation, or only starters, of foundation,

instead of fully built combs; and when the honey comes in freely, the bees can not build out the foundation fast enough to hold it; and much of that coming in from the fields is put into the brood-nest until there is not room enough for the queen to lay; and the first thing we know, under such conditions swarming begins."

"But does not a young queen assert her egg-laying proclivities even under these conditions, so the colony is slower in making preparations for swarming than a colony having an older queen?"

"After years of observation, I believe that such is the case. But just why a year-old queen should so assert is something I do not see any adequate explanation for; but I believe it to be a fact all the same; and in this we find a presumable reason why young queens are less likely to swarm than older ones. But let us not forget that more bee-keepers work for extracted honey than for comb honey; and with them the case is different. That changes the condition entirely. If enough empty combs are given, the queen will not be crowded, but she will have all the space needed in which to lay; and, no matter whether she is one, two, three, or even four years old, there is not likely to be any swarming until she begins to fail."

"But do not bees swarm when worked for extracted honey?"

"Not when managed right. Quinby gave us the secret nearly half a century ago when he said, 'Give a swarm in a box the inside of which is a cube of four feet; and if the swarm is large enough, or the apiarist helps the bees to fill that box with comb, swarming will rarely result; but if that swarm builds comb in only 2000 cubic inches in one corner of the box, the bees will swarm in future years about the same as they would in a hive of the 2000-cubic-inch size, the empty room outside of the comb built having very little influence upon them.' It is the amount of empty or fully built comb that is important. My experience is that, where combs are supplied so that the queen has all the room she can use for egg-laying, and at the same time such comb supplies all the room the colony wishes for the storing of honey and pollen, such a colony will never swarm, no matter how numerous in bees it becomes, even if beyond 100,000, nor how old the queen is."

"But we can not use such a large amount of comb as this when working for comb honey."

"Correct; and now we are getting back to where we started. Because the using of lots of comb in the brood-nest is unprofitable when working for comb honey, many have swung to the opposite extreme and have used very small hives. Where such hives are used it takes no very keen vision to see that the most prolific queens, usually the youngest, will fill all of the available space the quickest, and swarm the first and most often. In fact, an inferior queen might have all the space needed, and not swarm when in a hive too small for a better queen."

## GENERAL CORRESPONDENCE

### SOME OBSERVATIONS ON MARKETING HONEY.

**Unequal Distribution; the Uninformed  
Bee-keeper and the Devious Methods  
of Some Honey-buyers the Source of  
Low Prices.**

BY OREL L. HERSHISER.

Within the past fifteen or twenty years there has been a constant and marked advance in the price of nearly every thing the bee keeper has to purchase, including food stuffs and bee keepers' supplies. In many instances the advance has been upward of 50 per cent, as in the case of meats, dairy products, and lumber. On the other hand, there has been comparatively little advance in the price of honey. As long as the expense of consumption and the proceeds of production remain out of equitable proportion, and until the product of the apiarist has an exchange value for a just equivalent in other goods, so long ought the conditions and influences that control and make the prices of honey remain the subject of profound and earnest study and discussion by the bee keeper.

In the marketing of honey, three general classes of prices are recognized; viz, the jobbers, the wholesale, and the retail. When the dealer purchases from the producer the jobber's price is paid. The dealer or packer sells at wholesale, and the grocer or other distributor sells at retail.

Sales made by the commission merchant are made on the jobbing basis if of considerable volume, in which case the producer receives the jobber's price less commission. It is almost needless to say that the producer who sells through the commission merchant nearly always receives the lowest of all prices. If the producer jobs his honey by direct sale to the dealer there is opportunity for a clear understanding as to the price, and he is in position to know just what he is to receive.

By reference to some recent market quotations it is noted that "No. 1 and fancy comb honey would bring from 14 to 16 cts. delivered, such honey going to the retail grocery trade at an advance of from 2 to 2½ cts. on the prices quoted." It may be inferred that this advance, amounting to approximately 15 per cent, is the usual gross profit when selling at wholesale. Lastly comes the retailer's profit of from 25 to 75 per cent on his purchase price when sold to the consumer.

The retail trade does the greater part in distributing, and the dealer and manufacturer furnish a market for the larger part of the product. It is recognized that the wholesale merchant, purchasing in the jobbing way, and the retailer, are valuable factors in trade,

and that they present avenues through which a large portion of the world's production, of all kinds, can readily reach the consumer.

It is also recognized that prices of most commodities are fixed by the inexorable law of "supply and demand," which, like the laws of the Medes and the Persians, "altereth not." However, there are some exceptions, which, when closely studied, are found to prove the rule. Supply and demand, in these later years, have come so much under artificial influences, such as trusts and combinations in restraint of trade, either under contract or by tacit agreement, that there may be scarcity because of goods withheld from market to create a corner and oversupply because of artificially glutting the market to "freeze out" a rival. Sometimes, when there is a normal supply on the whole, markets in one quarter are glutted while in another locality they are bare, due to unequal distribution.

The honey market is often adversely influenced by merchants purchasing from the unwary producer his crop of honey at a ruinously low price and selling the same at retail, as a leader, at a small profit. Thus, recently one of the leading stores in Buffalo was retailing a fancy grade of comb honey at 17 cts. which, no well informed bee-keeper will dispute, is far too low for this season of scarcity of fancy honey. A leading store, by one or two purchases of considerable volume from uninformed bee keepers, can thus exert a powerful adverse influence on the market.

The devious methods of some honey-buyers are fruitful of market depression. The aim seems to be to create an artificial competition of the producers rather than to work the other end of the market by establishing prices at the normal level. The dealer writes to his list of honey-producers asking the amount of his crop and for a quotation of his price. After a few lots have been purchased of the producers making the lowest quotations, the scheme is to try to establish the low price by reporting large supplies and an easy market in consequence. If every producer would seek reliable information of the editors of bee journals or crop committees, and not make a price until well informed, and then, in answer to all such queries, quote the price that is advised; and, instead of disclosing the amount of his crop, ask "How much do you wish at that price?" *and stick to his price*, I think it would have a salutary effect on market conditions.

Another ruse, recently noted, was to make as low an offer as possible, and yet have hope of getting some shipments, with the luring and innocent looking offer that "if I can do better than this, or if market justifies it, or, in other words, if I have to pay others more, I will pay you more likewise," making final settlement afterward. Of course, out of a large list of bee-keepers enough, shipments are likely to be made to relieve the dealer of any obligation to pay a higher price, even if the crop and conditions were

such as to have caused a considerable rise. Bee keepers are advised to analyze and consider thoroughly their correspondence with dealers, and to consign to the fire all such conditional offers and the accept-by-return-mail sort as well.

One of the greatest obstacles to be overcome, if better prices are to be realized, lies directly at the door of a goodly number of bee-keepers. To illustrate, one of our best bee-keepers, having sold his crop of honey early in the season, wrote an urgent letter asking me to send him a sample of a certain grade of honey and to quote price. In reply a price was named, not above current quotations, as it was not strictly a table honey in this market. The answer received was to the effect that he could not purchase at that price—that he thought he had sold out at too low a price, and that he would lose money by purchasing. That the crop was sold out early in the season, and the price established at a figure so low as to preclude paying the jobbing price to fill small orders, shows plainly where much of the trouble lies.

*Hear ye, you bee-keepers who are producing fine honey and selling it retail at jobbing prices!* can you not see that you are working an injustice to the whole fraternity without any benefit to yourself? for if you are obliged to or prefer to sell at jobbing prices, then you can get as much from the dealer, and you will be money ahead in the end if you charge the wholesale or retail price according to the classification of your customer, and the amount sold for what you dispose of in a small way.

You know that honey is nectar secreted in the blossoms of numerous plants, and gathered, stored, and ripened by the bees; that it is the purest and most wholesome of sweets; that it comes direct from the hands of the Creator, perfect in every particular, while all other sweets require the intervention of man, machinery, and usually the use of chemicals in their preparation for use; that physicians frequently prescribe honey for their patients, and deny them sugar and other artificially prepared sweets, which plainly shows that scientific men who know, regard the latter as unwholesome and injurious in many cases where the former is wholesome and beneficial.

Kenmore, N. Y.

### THE HIGH COST OF LIVING.

#### Too Many Retailers for the Number of Producers; Co-operative Selling.

BY OLIVER FOSTER.

The steadily increasing cost of living has aroused the people to such an extent that the problem is a national issue. Secretary Wilson has given some of the vital facts in the case. The corporations and trusts are not entirely to blame, though they are no doubt responsible for the failure of Congress to revise the tariff downward. This end of

the argument concerning high prices has been the subject of thousands of newspaper articles and editorials. What I say will not deal with this, but will be along the line Secretary Wilson took when he stated that the retail price of meat was thirty-eight per cent above the wholesale. The waste of time and effort in the small shop is very great, and should have the serious consideration of all thinking people.

The retail business in meat and groceries is tremendously overdone. The statement of commercial agencies, that ninety-five per cent of men in business fail is easily believed when one looks at the men who go into the grocery business because they have the mistaken notion that any one can keep store. Farmers, gardeners, tradespeople, etc., buy a stock of groceries for five or six hundred dollars, and proceed to embark in business. The unfitness of this class of men "to make a go" of retailing is shown by the statement when I approach them on the honey proposition: "Oh! we can't sell honey, for we never have any call for it." And no wonder. Their idea that business would come to them unsought shows *why* they can't sell.

The man who is a real merchant is always willing to give a little time to look into every proposition to see if there is a chance to *create a demand* for the article among his customers. If the goods are choice, such a merchant will display and push the line among his customers.

But most of the retailers are of the small variety, not having enough business to keep themselves, their help, nor their horse busy half the time. It costs just as much whether the ice box holds two tons of meat or only a few links of sausage; the ice melts just as fast, and ice costs money during the whole year. There are something like seven hundred retailers of meats and groceries in Denver. One hundred could do the work better at a great saving in operating expenses. To have the most economical methods in operation we need something like the public-utility corporations in charge of the retail meat and grocery business of cities. I do not think a large corporation in control of the retailing business would be likely to lower prices unless forced to do so by legislation, but the business would be carried on in a more sanitary way. The ice-boxes could be larger, and the order that comes out of system in management would give us better food.

The great number of retailers who are merely existing in the grocery business could more profitably join the ranks of the producers. The producers could very easily form co-operative associations with city stations for distribution. The lines that could be handled might include milk, eggs, cheese, butter, honey, and produce of all kinds. This is practicable now, as many creamery companies composed of farmers are selling all these kinds of farm produce from their city stations. As yet nothing has been done to bring about a more economical management in the distribution of meats and gro-

ceries; but perhaps when the farmers are selling the bulk of their produce through the associations they will launch into the retailing of these too, and will own their own packing-houses and also turn wheat at a dollar a bushel into breakfast food at ten cents a pound.

Denver, Col.

### THE VALUE OF VISITING,

Some Good Ideas Picked up from Various Bee-keepers, and Passed on to Others.

BY F. GREINER.

The time of the year has come when we can give a little more attention to the theoretical part of our business. We have three ways: 1. Reading and studying; 2. Attending bee-keepers' conventions; 3. Visiting other bee-keepers. A great many bee-keepers do not avail themselves of all these means, particularly the last. In a conversation with some friend we can sometimes learn a valuable lesson, or start our thinking faculties in an altogether different direction with benefit to ourselves. By rubbing up against others I have picked up some good things of late, and I wish to tell the readers of GLEANINGS about it.

#### FRESH FOUNDATION THE EASIEST FOR THE BEES TO WORK; DIFFERENT METHODS OF PUTTING IN FOUNDATION.

By dear lessons many of us have found out that bees are loath to take hold of old foundation, particularly if it has been in the hives previously, and not drawn out. My aim has always been to procure freshly made foundation in the spring, and not put it into the sections till the honey season has arrived. The untouched starters in kept-over sections I always cut out and replace with the fresh article.

In talking with S. D. House, of Camillus, N. Y., I found that he had noted a great difference in the willingness of his bees to accept and draw out old as against new foundation; and his practice is to fill his sections with fresh foundation the very day he wishes to put them on his hives. If the conditions are such that the bees will begin to work on the wax at once, a great deal is gained, as all of us well know, and this is what Mr. House is aiming at. Bees are always more inclined to go to work on old foundation when placed in the brood-chamber; and the difference, he says, between the new and old article is not so apparent.

Before we had the Daisy or similar handy comb-foundation-fastening machines we secured the starters in the sections by dipping into melted resin, etc. We could clean and fill our wide frames (section-holders) with the made-up sections any time during the dull season when we had plenty of time. When we needed the supers, the starter could be quickly put in, handling the sections by fours. Since using the Daisy foundation-

fastening machine we can not follow this practice, and we therefore have no way of putting starters into sections by machine when said sections are in wide frames with separators nailed on the frames. If I understand it, the Root Co. is offering a wide-frame super in which the separators are a separate fixture. The Betsinger super, with its screen-separators, which Mr. House is using, is so constructed also. Such supers offer the advantage that they may be gotten ready during the winter for use in the apiary except putting in the foundation.

Mr. Betsinger's method for putting foundation into sections was as follows: His wide frame held three sections. This was placed upon a board to which were fastened three square blocks a little less in size than the inside of the section, and so spaced that the sections fitted nicely around them. These blocks were a little less in thickness than half the width of the section. The properly cut and well-fitting foundation was next placed upon the blocks and inside of the sections. With a little ladle some melted wax was dipped up, and with it the sheets were secured to the wood, allowing the hot wax to run along the top of the section as well as part way down the sides.

This process seemed to me a rather slow one. I also objected to so much wax being used inside of each section. Mr. House improved on the plan inasmuch as he fastens the foundation with a hot iron plate, *a la* Daisy, but without any machine. The iron plate is attached to a handle, the whole thing resembling a huge putty-knife. Several such are kept heating over a small kerosene-stove, and are changed as often as necessary. [This is just the principle of the Root foundation-fastener.—ED.]

We who use wide frames with separators nailed on, or also section-holders, must handle the sections one by one when putting in the starters or sheets of foundation, and after that we have to put them in the frames. Here we run into another snag. Sections do not always fold absolutely square, and are not rigid enough to admit putting in exactly fitting sheets of foundation. Mrs. Bacon, of Waterloo, overcomes this by cutting her foundation sheets slightly bias, or just a little narrower at the bottom of the sheet, using a pattern to cut by. I would make a miter-box so that I could cut 12 or 15 sheets at one operation. Of course the strips of foundation would have to be of just the right width, or about  $4\frac{3}{8}$  inches wide for the 4x5 sections. I think I shall practice this plan if I ever use full sheets of foundation in my sections.

#### THE PUTTY-KNIFE FASTENER.

The House method of using the putty-knife-fashioned plate instead of a machine commends itself for several reasons to those whose super fixtures admit of such a plan. When putting in starters or full sheets with the Daisy we have to work very lively. A section must not be left on the machine a moment longer than is necessary to operate the hot plate. Sometimes the foundation

becomes warm and limp before we can go through with the operation. This gives us trouble. Such does not and can not occur when we practice Mr. House's method. We may leave the sections on their form any length of time. In fact, it is a good idea to use several forms and leave the sections after the starters are put in a little while (long enough for the wax to harden) before taking them off.

One may also employ inexperienced help. An eight-year child may put the wide frames on the forms and drop the sheets of foundation in while the experienced hand attends to the work of fastening the foundation with the hot plates.

#### A SOLAR EXTRACTOR WITH A LAMP IN COMBINATION.

When visiting my brother, G. C. Greiner, last fall I noticed his solar wax-extractor. It was built on the Doolittle solar plan with some alteration. A fine-meshed screen was supported just over the iron bottom, upon which the comb to be rendered was placed. Under these conditions it was found that old Sol did not have power enough to do a thorough job, and so he added a lamp to the outfit, thus making it complete. With this machine he secures good-sized cakes of fine wax which do not need recaking. However, he uses only cappings in the machine, and they are first washed free from all honey, and then dried.

#### WHAT IS THE NEED OF A HONEY-STRAINER?

Among other subjects discussed at this meeting was the honey-strainer. I asked him where his honey-strainer was. (I mistrusted that he had not observed or did not appreciate the great (?) progress that had been made in that line.) Without a word he pulled a glass jar of honey from a crate at random and held it up to the light. The honey was water-white, and most beautiful. Not a speck nor an air-bubble was in it or on top of the honey. "Has any living man or woman ever produced any thing finer than this with any strainer that you know of?" he asked.

"I think not," I answered.

I had to acknowledge that a great deal of energy seemed to be uselessly expended in building complicated honey-strainers and putting honey through them with no visible effect or the slightest improvement over honey not strained but simply drawn through the faucet from the bottom of the tank. If the tank is narrow and tall, nearly all foreign matter can be easily removed with a spoon when it is full. Some honey will be dipped up at the same time; but if we put the skimmed matter into a pail, after a little time the larger part of the honey may be poured out by holding the pieces of comb, scum, and sealings back with the spoon. A better way would be to use a small tank having a faucet at the bottom. After all the skimmed matter has been collected in this, and after giving time, about all the honey could be drawn off.

I have strained my honey through a cloth,

but never obtained a perfect article. Metal sieves can not do better. In fact, it is an impossibility to free honey quickly from the very fine particles of wax which it always contains. A little time does it. Honey drawn from the faucet at a summer temperature flows easily and without even leaving air bubbles on the surface. I fail to understand why such men as Mr. Alexander, for instance, recommend straining honey. That portion of honey which is drawn from a tank last, no matter whether a strainer has been used or not, is not fit for bottling. The tailings of several tanks may be run into one small tank and given a little time to clear. In the end there will be very little left but what is fit for bottling.

#### A BETTER MILLER FEEDER.

An improvement in the Miller feeder was suggested to me by W. F. Marks. All who have used this feeder have undoubtedly observed that there are times, particularly when the hive is not leveled perfectly, when a little of the syrup is inaccessible to the bees. Let the feeder be so made that the bottom inclines to the center just a trifle. The bees can then take out the very last drop.

#### FINDING QUEENS IN LATE FALL.

There seems to be a feeling among quite a number of bee-keepers that purchasing queens in the fall is not advisable. Some expressed themselves in strong terms, saying they did not want late queens as a gift. The fact is, it is any thing but a pleasant job to take a colony apart in order to find the old queen. The bees are cross, therefore difficult to keep in subjection. The combs are heavy, and are often set to leaking, thus attracting robbers. Mr. House offers this solution: Drum or drive the bees into an empty hive-body placed on top of the hive containing the colony to be dequeened. When the bees have clustered they are dumped out in front of their hive after adjusting an entrance-guard. The queen is thus found easily, no honey set to leaking, etc., and the new queen is then introduced or run in as is thought best.

Naples, N. Y., Dec. 18.

[We believe it is generally acknowledged that fresh super foundation is more easily worked than that which is a year old. Some discussion a few years ago seemed to show this quite plainly.]

As to whether extracted honey needs a strainer depends on conditions. We have been in quite a number of large extracting-yards where honey was produced by the carload; and many (if not a great majority) of those big producers use honey strainers and settling-tanks both—a strainer to catch thearser particles, like slices of cappings, brood, and drowned bees, and a settling-tank to remove the finer particles that can not be secured in any way but by the force of gravity. The strainers undoubtedly do save time in that they catch the great bulk of foreign material that would go in with the honey; and where said honey is conveyed quite

a distance through a tin conductor, a strainer is indispensable. Many producers, to save handling, do use such a conductor from the strainer to the settling-tank. You will remember that Mr. Alexander conveyed his honey from the extracting-house through a tin pipe on a slight downward grade to a large tank some distance away. As he produced mainly buckwheat honey, or buckwheat mixed with aster, a dark honey like this does not need a settling-tank nearly to the extent that a light honey does.

Queens reared late in the summer or early fall may not be the equal of those reared early in the season; but there is no reason why they *may* not be just as good, providing the cell-building colonies are fed liberally during the time when the cells are being supplied with royal jelly. But this is not all. Liberal feeding alone will not produce strong vigorous queens. A colony *must* be put into condition where it will be queenless and broodless—that is, fairly *cry*\* for a queen before it will do its best work in cell-starting and cell-building. An up-to-date queen-breeder who knows these tricks of the trade can, if he chooses, furnish just as good queens in late summer as during the early part of the season; but the probabilities are that the average queen-breeder does not furnish late-summer stock that is equal in every respect to that which is reared earlier when conditions naturally are more favorable. It is too much work.—ED.]

## DO BEES STEAL EGGS?

### Laying Queens that Developed from Stolen Eggs.

BY E. C. FRAZIER.

On page 780, Dec. 15, I find some assertions made by Mr. Samuel Simmins, with which very few practical bee-keepers of America will agree. I am very certain that at one time I knew of bees stealing eggs. Of course I did not see the act accomplished, but I will explain.

In the year 1879 I lived at Sacramento, McLean Co., Ky., the first time I tried to use movable frame hives. I first bought a farm right to make and use the N. C. Mitchell "Long-idea" movable frames. I made my own hives and frames, and, what a fit! and, of course, being green, for I had never seen a comb transferred, I mashed bees, combs, and a queen. I transferred five hives for myself that season. I killed one queen in transferring, and knew when I did it. In handling the comb I mashed her accidentally; and when I ran the bees into the hew hive I dropped the dead queen down between the

frames of comb. The next morning she was pulled out on the alighting-board. Those were the brown German bees.

Mr. Mitchell taught in his books that, if there were eggs or very young brood, the bees would raise a queen; but these bees did not do it. I left the colony alone for some time, as it was very strong. In the meantime I had sent for two pure Italian queens. When these came I clipped them and introduced them in two of the hives, and in due time I had Italian bees flying from both hives; and now comes the strange part to me. The colony whose queen I mashed was dwindling. I examined it and found all the brood hatched with the exception of some drone brood in worker cells. I closed the hive after looking through it, and examined the rest of the hives that day; but in a few days I went back to the queenless hive and opened it again; and, imagine my surprise when, on the edge of a comb, I found a fresh queen-cell about half-finished with royal jelly in the bottom, and a young larva floating in the jelly. I hastily closed the hive and beat a retreat in double-quick time, as I had no veil or gloves.

Surprise No. 2 came in about three weeks. My father was at my house, and we were out looking at the bees, when he said: "Ras, you have a fine queen in that hive; look! Isn't she a beauty?" And she was as pretty an Italian queen as one would wish to see. She had come out to mate. In about 20 minutes she alighted on the alighting-board and went into the hive with a white-looking thread attached to her.

About a month after that time, father and I looked into the hive where we saw the young queen enter, and there were several young Italian bees crawling over the combs, and a nice lot of brood, capped and uncapped, and eggs in the hive. I told father about the hive being queenless, and he said, "Oh! they stole an egg from one of the other hives; they sometimes do that."

The two Italian queens I bought were the first and only ones brought into that country at that time and for some time after.

I wish to ask Mr. Simmins and other bee-keepers some questions:

Did you or any other practical bee-keeper ever know or hear of the eggs of a laying worker hatching any thing but a drone? Mr. Simmins says, "I can see no other possible explanation than that laying workers are responsible." Now, I have taken the young larvae from as many as half a dozen queen-cells, and replaced them with eggs of the laying worker, and all from one cell, and drones developed in them every time. The experiment was tried on a hive that had cast a prime swarm two days before, while I have tried the same experiment three or four times with the same results. A bird or fowl of the female sex can and does lay eggs without the male; but all know the eggs will not hatch; but the laying-worker bee can and does lay eggs that hatch drones; which, however, are useless because they can not fertilize a queen-bee. If any one thinks they can, let him winter a hive or two of them

\*By this we mean put up a roar of distress—distress for what seems to be a hopeless condition. When a bar of freshly grafted cells is given, their chyle-secreting glands being surcharged because there has been no brood to feed, they immediately jam the cells with chyle food. A well-fed baby has an immense advantage over one that was poorly fed at the start, whether it be an insect or animal.

and try them with virgin queens in the early spring before any other drones begin to fly. I have tried this experiment twice, but have failed to get a single queen fertilized.

Adams, Tenn.

### PURE STOCK VS. HYBRIDS.

**Is it not Better to Breed from the Best Colony in the Yard, Irrespective of Race?**

BY FRANK C. PELLETT.

Inasmuch as my experience with the Italian bees has been so different from that so often expressed in your columns, I feel impelled to offer a word in favor of the hybrid. Every one seems to have the idea that the only thing to do is to Italianize and keep only pure bees, or as nearly so as his locality will permit. I am inclined to the opposite view. With about one-third of my apiary of the yellow bees, they have not, so far, proved as satisfactory as the darker ones. Fifteen of the queens originally came from a breeder well known, and one who, being a regular advertiser, probably has sold queens to a large part of the readers, so we feel sure the fault can not be with the strain. However, not all the queens came from him, and we can see no appreciable difference between those queens (or, rather, colonies) and the other yellow colonies.

There has been much said in these columns about the gentleness of the Italians; but the crosslest colony we have are yellow bees; and the gentlest (or as gentle as any) are dark hybrids. Do not understand me to say that all our yellow ones are cross, as some are not; but we have no dark bees that will come as near driving the whole outfit out of the yard as the above mentioned colony of yellow ones. Then the best honey producers we have are hybrids and they make the cleanest combs with less propolis and less bracecomb. We can take off a super and feel pretty sure that none of the combs are fastened to the separators. The worst bees to daub propolis over the sections and attach the combs to the separators are in almost every case among the yellow ones. The most expensive queen we ever had was a failure excepting in the color of her offspring. They were unusually yellow; and if beauty is worth any thing she was worth the price; but the colony finally died late in spring from dwindling. There is only one thing that, in my experience, has been in favor of the pure Italian; and that is the ability to resist the bee-moth, which they seem to be able to do better than the darker bees.

#### MOTHS DESTROYED THE EMPTY COMBS.

Speaking of the bee-moth leads me to tell some more experience. Last winter we purchased a number of colonies of bees that were short of stores. These we fed until after fruit bloom, when they had quite a little honey on hand, and we supposed them safe for the season. However, June was

cold and wet, with hardly a day when the bees could get out until the last week in the month, and, before we knew it, our colonies were dead. As we run only for comb honey, surplus combs are rare with us, and we had read somewhere that, if placed two inches apart, the moths would give no trouble; so we took a lot of empty hives and put in occasionally a comb between empty frames. We lost the whole lot. Had we been a little more careful to look after them, and placed them over our yellow bees, we could have saved the combs.

From our experience we have decided that, instead of requeening with pure Italian stock, it would be better to do so from the best all-around stock in the yard, regardless of color, race, or origin. There have been so many Italians introduced into this section that it would be difficult to find any of the black bees not more or less mixed with them.

Atlantic, Iowa.

### SETTING BEES OUT OF THE CELLAR.

**The Effect of the Wind on the Drifting of the Bees.**

BY E. D. TOWNSEND.

In a Straw, June 15, 1909, Dr. Miller says: "It may be that 'if there happens to be a heavy wind it is liable to force the bulk of the flying bees toward the leeward side.' I don't know. I never took bees out in a heavy wind. I couldn't be hired to do so."

I understand perfectly, doctor, that you never took bees from the cellar during a windy time or you would not have left the impression in the foregoing that bees drift to the leeward in their first flight after setting out of the cellar, especially if they have not wintered well.

Many bees leave their hive without any apparent thought of returning; or, in other words, they do not mark their location. In this case, if a heavy wind is blowing it sometimes seems as if nearly all the bees in the air are being blown off to leeward; and one would think they would surely enter those hives where the bees are flying so thickly. They won't, though. It is something like this: As the gust of wind lets up, the flying mass of bees will hover around the row of hives at the leeward side of the yard. They actually expect (according to their actions) to enter this leeward row of hives. However, as they hover in front of this row the "homing hum" is blown away from them, and the bees hear only the call of the bees in the hives to windward and they fly over to this next row only to hear the hum or call of the bees entering the hives further on to windward. This moving over to the windward is continued until the throng is drawn over to the windward side of the yard. The windward side, not the leeward, then, is more likely to draw more than the proper share of bees.

Remus, Mich.

## MODERN APICULTURE IN MEXICO.

BY CARL LUDLOFF.

From "Mexican Industries," Monterey, N. L. Translated from the Spanish by Geo. W. Dithridge.

At a time not far distant the art of modern apiculture will be one of the most important branches of agriculture in the republic of Mexico. Up to the present time this industry has been carried on in an antiquated manner, generally by the Indians, as a business exclusively in the hot zone of this country, while in the more elevated temperate regions it is regarded as a diversion wholly without a business prospect.

The cause of this apicultural situation is that the tropics in general produce a class of honey suitable only for exportation, and used principally in the great industries of the countries of the North; but rarely does one encounter a quality of honey appropriate for the table, while the wax, secured by the crude methods employed, is of much greater value than the honey. It is to be inferred that even modern bee-keepers have not been disposed to improve the ancient methods, nor to establish their colonies on modern scientific principles.

On the other hand, the very remarkable and singular conditions of climate in the temperate and cold zones of Mexico up to to day have rendered it almost impossible to protect the bees in any known hive. It is considered to be not only certain but beyond remedy that the colonies of bees are to dwindle to almost none, or to disappear entirely during the winter season; and bee-keepers are obliged to commence almost entirely *de novo* every year with the remnants of their colonies. This is the reason why extensive bee-yards are unknown in this region, those of from ten to forty hives being considered rare exceptions. The yards, as a general rule, contain no more than from one to five colonies, usually in a most deplorable condition. That such a style of bee-keeping can offer no inducement to any one to waste time, labor, and money in it needs no assurance or explanation. But the honey produced in this zone is of such excellent quality, and the quantities gathered by the bees so great, in spite of every obstacle, that it remains only to discover a method of management to render it possible to develop apiculture to a state at least equal to that of other countries. Such difficulties have been wholly overcome elsewhere.

Before discussing this question it seems necessary to limit ourselves to the consideration of good honey and of inferior honey. The zones of these honeys are found at certain elevations above the sea. Commencing at the ocean or gulf shore, the inferior honey is found to a height of 5000 feet, corresponding to the region adapted to the cultivation of sugar cane. In this region the life of the colonies is irregular because of the issue of swarms at any time of the year, more or less, and this appears to be the principle object of bee energy. The accumulation of

honey is an object of secondary consideration, because the bees are accustomed to encounter it in a junctance at all times. They have neither time nor inclination to accumulate quantities of honey. This is well enough, but it is not exactly what we want.

From the zone of sugar-cane culture, divided by an inclined plain of several hundred feet of elevation, being the transition zone, which is the habitat of the maguey or pulque plant (*Agave Americana*), commences with exactness the zone of fine honey. In this region a plant known by its Indian name of "chayotillo" (*Scisios edulis*) is found in vast numbers, blossoming in the rainy season. At the same time, there is also found in this zone a plant of the family *Cucurbitaceæ*, and this is the appropriate Mexican plant for honey. In every locality where this plant is in abundance, apiculture may be regarded as a sure and certain business. In addition to the chayotillo, the mesquite trees and shrubs yield in the beginning of spring a splendid harvest of honey. The honey of the chayotillo belongs in the highest grade of honey known in all the world, and surpasses the famous honey of Colorado and California. On this account apiculture in this elevated section of Mexico should be esteemed a very remunerative business, but only by the use of hives and strains of bees entirely adapted to the climate. This subject will be considered further in the March issue of this journal.

Vencedora, Chih., Mex., April 30, 1909.

---

 THE BULK OF THE HONEY COMES FROM WITHIN ONE MILE OF THE APIARY.

There is some discussion in the bee journals of late as to how far bees go for pasturage; and I agree with those who claim that most honey is gathered within one mile from the apiary. I have an outyard which is about three miles, at least not exceeding  $\frac{3}{8}$ , from my home yard, and I have more than once secured a fair honey crop there while I got but little honey in my home yard.

## STRONG QUEENS FROM TWICE-GRAFTED CELLS.

Noticing the article, page 763, Dec. 15, on breeding strong queens, by J. W. Savage, I will endeavor to relate my experience. On the 10th of June, 1909, I found two colonies that had small queens. They looked like runts or as though they were half starved. I experimented by removing the queen from one of them, and in a few days I examined the colony and found six queen-cells about  $\frac{1}{4}$  inch long. I removed the larvæ, putting in their places younger or smaller ones, and trimmed the cells back so they were not over a third as long. Before putting in the next larvæ I smoothed the royal jelly down with the ivory tip of a leadpencil. In two days I examined and found the bees were working on the grafted cells and putting royal jelly in them. I removed the other small queen from the second colony and grafted one cell in that hive. The result was two strong and fine-looking queens; and it did me great good to see the colonies grow to two strong ones. One colony produced 186 lbs. of first-class honey, and the other 158 lbs.

My experience proved beyond doubt that the Nektart and Perkins method is all right, and our thanks are due to Mr. J. W. George for bringing it before the public. I tried almost the same method fifteen years ago in Washington, but did not trim the cell back, and did not have as good success as this time. The two colonies mentioned belong to Mr. J. B. Ferrine, Blue Lakes, Idaho.

Jerome, Idaho. S. F. BAILEY.

THE CHIEF INSPECTOR OF INDIANA LOOKING FOR FOUL BROOD.

### INDIANA'S FOUL-BROOD LAW.

Some Figures Showing the Excellent Results from the First Year's Work; Some Amusing Incidents Connected with a Foul-brood Inspector's Work.

BY WALTER S. POWDER.

Our new law placed the work of inspecting apiaries in the hands of our State Entomologist, Mr. Benjamin W. Douglass, and the work required from his office takes in a wide scope. Mr. Douglass appointed Mr. George S. Demuth, of Peru, Ind., as chief inspector of apiaries, and where required deputies were appointed. Much valuable work has been accomplished; but when we scan the figures which will appear in the annual report we realize that Indiana did not take the work in hand any too soon.

We recently asked Mr. Demuth for some statistics on the first season's work, and he informs us:—"During the season some inspection work was done in each of twenty-two counties. A total of 513 visits were made, and 480 apiaries were visited; 6036 colonies were inspected; 1431 of these were diseased. Of the 6036 colonies inspected, 328 were in box hives and 213 were in frame hives from which combs could not be removed on account of being built crosswise. Some of these were even in 'Pouder's Best,' but I presume the owners' wives had appropriated for ner flatirons the foundation which you sent along; at least there was no evidence of any having been used in the frames."

We then asked Mr. Demuth a number of questions, the answers to which, together with the questions, are as follows:

"Do you find hives and combs exposed to robbers in which the bees have perished?"

"Yes. In addition to the 1431 diseased colonies, 495 hives were found from which the bees had died of foul brood and were left exposed to robbers. In many cases robbers were found at work on these combs when the inspection was made, as colonies continue dying during the entire season. In the 495 hives the characteristic scales of American foul brood were discovered. Many other hives of combs were found exposed to robbers, but only those known to contain disease were counted in the 495. The 495 hives were not counted in the 6036 colonies inspected. These hives and combs were promptly burned before leaving the premises."

"Have you found it necessary to destroy any living bees where owners failed to comply with the specifications of the law?"

"Fifty-eight colonies of bees, hives, and combs were burned during the season. No bees were burned unless the owners absolutely refused to treat them."

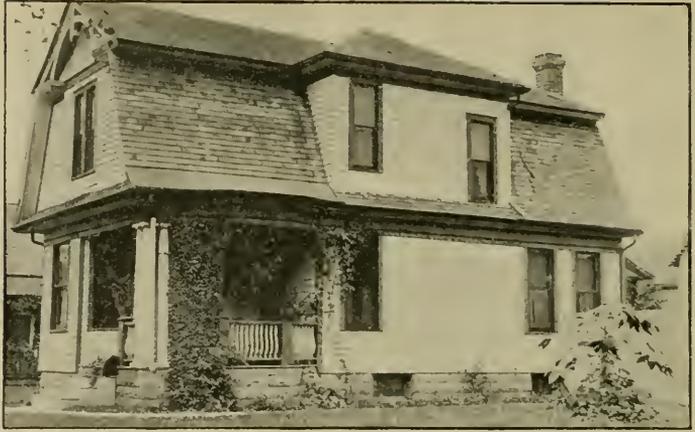

"Have you met with any difficulties or unpleasant features in enforcing your instructions?"

"A few peculiar features developed from time to time, but they were more of a humorous nature than unpleasant. I recall having wasted a valuable half-hour in trying to convince one man that we had a legal right to inspect his bees, and that each colony

would not hie away to parts unknown, or would not wither under our deadly touch, and shuffle off to the happy hunting-grounds. I was so indiscreet as to intimate that we would inspect the bees any way. At this the man burst into a mighty wrath, and, stretching his 'six-foot-two' to its full height, he remarked, 'I fought three years to save my country, and I shall fight three more to save my bees.' I took this as a signal to begin work, and immediately pried the super from the nearest hive and began removing brood-frames.

The soldier was so surprised that he only pouted like a child. On one occasion I had to burn some bees in a certain locality, and a few weeks later I happened to be in the same place, when, to my surprise, I learned that the farmer bee-keepers had heard of the awful man who went about as a roaring lion burning peoples' bees; and so, in order to save their honey and wax, they were actually killing their bees and rendering the honey and wax so the "awful man" wouldn't burn them. This happened in a neighborhood where no inspection work had been done whatever, and the bees were probably healthy. One man, whose bees were badly diseased, refused to treat them, so we went to destroy them. The owner came at us with a big butcher-knife, whisked it about my face, and informed me that if we killed his bees we must first kill him. That looked like a rather large undertaking; so we brought the town marshal to watch the knife while we had our backs turned doing the work. So far as I know that knife is still innocent of human blood."

George S. Demuth was born near Peru, Indiana, reared on a farm, and has kept bees since he was a mere boy. Like other bee cranks

MR. DEMUTH'S HOME IN PERU, INDIANA.  
This home was built with one season's profits from the bees.

he has eagerly devoured every thing he could get hold of on the subject of bee culture, and has spent considerable time and money in experimenting. He is quite thorough in microscopic work, and is an expert photographer, which is of much benefit in his present work. He owns and operates three outyards, a total of 200 colonies, all run for comb honey, using an automobile in visiting the different yards. He is the only one whom I have personally known to practice migratory bee-keeping successfully. By moving a carload of bees to the marshy regions for the fall flow he has secured excellent results; but the system had to be discontinued on account of foul-brood appearing in those regions. Since foul brood is to be eliminated, the practice will likely be taken up again.

He spends less time now on three yards than he formerly did on one; and while this has been his poorest season, the time required shows a fair profit. His best season was that of 1908, when he built his beautiful home from the proceeds of his apiaries for that one season.

During the cold months Mr. Demuth is kept busy inspecting nurseries and nursery stock, and much other work emanating from the office of the State Entomologist. The educational work which is being accomplished in favor of the bee industry is bound to have a telling effect. At our State Fair Mr. Douglass exhibited specimens of foul brood in glass cases, showing the disease in its different stages; also a half-starved swarm of bees clustered on dead-ripe grapes, and other interesting exhibits of bees which were in charge of Mr. Demuth. The lectures attracted large crowds.

Mr. Demuth's lectures before institute meetings, with his lantern-slides, are being spoken of as models of perfection. Prior to his appointment as Chief Inspector of Apiaries he had been employed as one of the professors in the city schools of Peru. It was an instance of "the office seeking the man,"

GEO. S. DEMUTH, PERU, IND.  
Chief Inspector of Apiaries in Indiana.

and the work accomplished is certainly a credit to the Hoosier State.  
Indianapolis, Ind.

[Indiana is certainly to be congratulated on having so efficient an inspector. One who knows his job and how to handle these ignorant bluffers and cut-throats, like Mr. Demuth, should be and probably will be retained in service.—ED.]

## BEES IN THE GARRET.

### One Colony in a City Averaged 75 Pounds of Comb Honey for Eleven Years, and did Not Cast a Swarm.

BY CHARLES STEWART.

Bee-keeping is classed among rural industries; yet it is not necessary to live in the country or even in the suburbs or in a village to taste the pleasure of the pursuit, for it is a genuine pleasure—it is even more; it is a delightful and seductive charm; and for the city man who retains many of his original illusions and all his love for the simple life of rural industry, keeping bees is the least depressing method of being "stung." A whole lot of enjoyment (and, incidentally, 50 or more pounds of honey) may be had from a single colony of bees in the most populous residence district of almost any city in that wide belt extending east and west, perhaps, from Montreal, Can., to the Gulf of Mexico. The place to keep the colony is in the garret, and a good time to make the start is during the swarming season.

Several years ago the writer's attention was first called to a colony of bees in the garret. No, they did not disturb the neighbors, for the neighbors did not know they were there. Since that time many others have come under his observation; and with all of them the result has been substantially the same. In no case do they require much care; and the rule is, *they do not swarm!* While the rule is not "iron," the exceptions are very rare. To the writer's personal knowledge, a colony that has been kept eleven years in a garret never swarmed; and during that time it averaged more than 75 lbs. of section honey annually. This is (for the colony is there yet) in the residence section of a city of about 20,000, the princely home of a retired oil and glass capitalist. The same man has also a colony in the attic of his stable where he keeps a few high-bred driving horses. The colony in the stable is on a shelf, or platform, at a slatted ventilator which affords the bees ingress and egress. It has been there nine years, and never yet has swarmed; and the honey produced has averaged about the same as the colony in the garret a few rods away.

Of the many other colonies of bees kept in garrets, only one instance has come to the writer's knowledge of their having swarmed. You can put a colony in your garret;

and if it has sufficient hive room, the chances are a hundred to one the bees will not disturb your neighbors nor dissipate your expectation of a honey-yield by swarming.

As good a hive should be used as though it were to stand out in the weather; and producing honey in a small way with one or at most only a few colonies, where extracting-outfits would prove impracticable, the hive should be suitable for the production of comb honey. True, shallow extracting-frames might be used instead of sections, and the honey cut out for use as "chunk honey," but it is not tidy nor neat, and in a short time the "proprietor" of even a single colony will experience a pardonable pride in having his bees produce as nice "section honey" as any to be seen anywhere. No mistake will be made in choosing the Danzenbaker hive. It is the comb-honey hive *par excellence*. Your colony in the garret, with abundance of winter stores, will build up to enormous strength early in the season and have a mighty army of bees to garner the crop of nectar from every source. They will need an abundance of hive room; and the Danzenbaker hive, being both a shallow brood-nest and a ten-frame hive, presents an admirable foundation upon which to tier up supers for surplus honey without fear of top-heaviness. The statement already made, that the average, in confessedly poor localities for honey-gathering, has been about 75 lbs., should not mislead; for in exceptional years the yield may be double, triple, or quadruple, and there should be supers enough on the hive for any contingency.

Toledo, Ohio.

#### ANNUAL CONVENTION OF THE EASTERN NEW YORK BEE-KEEPERS' ASSOCIATION.

The second annual convention of the above association was held Dec. 8, in the chambers of the Common Council, City Hall, Albany. The President, W. D. Wright, called the meeting to order. At the call of the roll of 53 members, only 20 responded. The minutes of the previous convention, held at Catskill, were read and approved. At the collection of dues, 20 members paid their dollars.

A motion was adopted making all dues payable from Jan. 1 of each year.

The President presented an interesting and entertaining address. The annual election of officers resulted as follows:

President, W. D. Wright, Altamont.

Vice-president, T. D. Mower, Athens.

Second Vice-president, A. L. Fisher, Central Bridge.

Secretary, S. Davenport, Indian Fields.

Treasurer, M. A. Kingman, East Greenbush.

The President, W. D. Wright, and Secretary, S. Davenport, were elected delegates to the annual convention of the New York State Association of Bee-keepers' Societies. The Secretary suggested the propriety of taking a statistical report from members relative to their bee-keeping and its results; but on soliciting the same some discussion developed much opposition, and the subject was laid on the table.

Geo. B. House, Black River, and Irving Kinyon, Camillus, delegates to the State convention, also Alden Hilton, Schenectady, made extended remarks on interesting topics.

The time of the convention was mostly taken up with routine business, as it was to be followed in the afternoon by the convention of the New York State Association of Bee-keepers' Societies.

S. DAVENPORT, Sec'y.

## ROBBER-TRAPS.

### How Constructed; When and How they Can be Used.

BY E. R. ROOT.

We have been using in our yards, for some years back, various forms of robber-traps. Their purpose is to catch the hardened "old sinners"—bees that are professionals in the art of robbing, and which are of but little practical value for the purpose of getting honey honestly from the fields. As we have before stated in these columns, we catch these shiny-backed bees and kill them. While some protest has been raised on the ground that they might be made over into a colony, yet the kind of "old sinners" to which we have referred are useless for *any* purpose. In a queen-rearing yard the sooner they are out of the way the better for all concerned. As long as they are allowed to prey on their honest neighbors they will *continue* to make work in the yard disagreeable by keeping every colony stirred up and more or less cross, despoil baby nuclei, and make trouble generally. But this is not all. They incite other bees to rob. The force of example is very potent among bees as well as human beings.

A short time ago Mr. Holtermann, in his department, facetiously remarked that any man who would use a robber-trap ought to be "trapped" himself—implying, of course, that such a device is a useless contrivance in a well-regulated apiary. As we later pointed out, robber traps are almost indispensable in a queen-rearing yard. While one does not need to use them continuously, they are required on occasions; for if a few bees once get started to robbing they will day after day pounce on the combs every time a hive is opened, and render life miserable for their owner and for the baby nuclei. Time and time again in our yards we have restored every thing to absolute order and quiet by the use of the trap. It works like magic; and after the rascals are caught, one will be surprised to note how *few* bees can make such an uproar as is evidenced by the number in the trap. Their intrinsic value is practically nothing, even if they were good honest bees. To let them loose would only invite more trouble. The amount of honey that they might gather if they could be "reformed" would be a very insignificant item. But the amount of damage that they can do in interfering with our

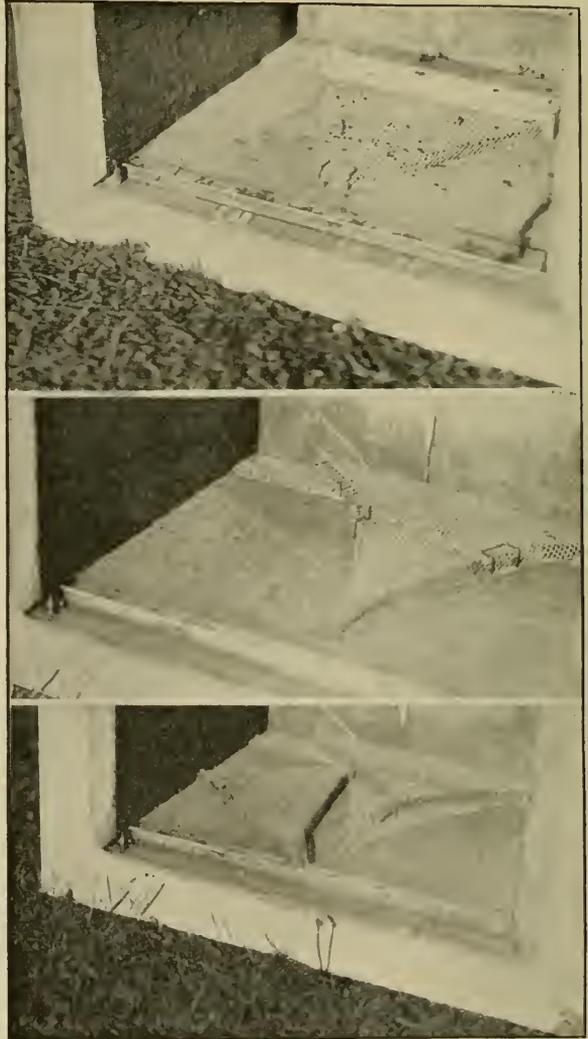

FIG. 1.—Wire-cloth-cone bee-escape on the inside of robber-traps. Note that the large end of the cone communicates with the regular entrance of the hive. Robbers pass in at the entrance up through the cone into the hive and are caught.

queen-rearing operations is no small item. But Mr. Holtermann comes back and says that, if a robber-trap will catch robbers, it will also catch *honest* bees, and why destroy good property? There is no need, Mr. Holtermann, for catching anything but the hardened old sinners—those that we consider hopeless beyond redemption. As explained, we do not run the trap continuously throughout the season—perhaps one or two days in a week, and not even then if no robbers show up. During the entire season at our home yard of 400 colonies and nuclei the total number of robbers that we catch would hardly fill a two-gallon measure; and we venture to say there was not one honest bee out of five hundred in the whole number.

How do we avoid catching honest bees? Easy enough. The traps are put in operation only when the prowling thieves are around. They are constantly on the alert, skilled as they are in the art of stealing and in finding any exposed sweets; that is to say, they are ever following one about, while the honest bees are either in the field or hive.

Let us assume a case. After we have been working in the yard a few days there are a few robbers that accumulate. But we do not let them continue on with their nosing into other people's business till they make work in the yard exceedingly disagreeable, and the colonies that are being worked cross. Before they become very numerous, two or three robber-traps are put into operation; and in an hour absolute peace is restored and not a prowler is in sight.

The value of the trap depends on the fact that it stops a would-be bad case of robbing *before* it has progressed to any extent. A little syrup (and a very little) is put into one or two traps. The robbers, because hunting for sweets, are caught *long before* any honest bees think of looking for it. If Mr. Holtermann will try the traps he will find there is no need for catching honest bees. If he does *he* ought to be "trapped."

#### CONSTRUCTION OF ROBBER-TRAPS.

Let us now look over one of these traps at the Root apiaries and see how they are constructed. An ordinary hive, such as is used in the yard, two wire screens such as are employed for moving bees, a super-cover, and a wire-cloth-cone bee-escape, make up the complete outfit. (The ordinary Porter spring escapes for this purpose have not been found to be as satisfactory as the wire-cloth cones.) We open up the robber-trap hive, and just over the entrance of it we find a wire-cloth cone tacked up against the inside hive-front. This is made by cutting and folding a piece of wire cloth in the form of a triangle. The large end fits over the en-

trance, while the other end, gradually tapering to a small orifice (about  $\frac{3}{8}$  inch square), reaches nearly to the top of the hive, or within an inch of the rabbet on which the frame-rest; it is then secured by double-pointed tacks as shown at the top of Fig. 1. As an additional precaution we find it desirable to have a smaller wire cone of the same construction under the larger one. Where there is only one cone the bees are liable to go back out through the entrance. Other forms of cones are shown in the two lower views of Fig. 1.

One of these traps is placed at a convenient location in the yard, when one of the wire screens for moving bees is laid on top. With a brush we smear a little diluted honey (honey is better than syrup) over the wire cloth at one end—the back one. This film of honey is spread over an area of about two inches wide by the width of the screen. Another screen is placed on top of this, and over the whole is placed a super cover as shown in Fig. 2. Notice that this super cover is set back about two inches, leaving a portion of the wire cloth—the part smeared with honey—exposed where the bees can get a *smell* of it, but not touch it, because the upper screen keeps them from it. Now, a robber-bee, if a hardened "old sinner" or a professional, when it smells honey in this way will immediately begin to "investigate." It will hover around the wire cloth (not covered by the super cover) for a minute or so, and then, like a duck to water, it will make a dart for the entrance. There are no guards there to stop it; it rushes in pell-mell, crawls up through the two wire-cloth cones shown in the previous illustration, and out through the apex, when it is a prisoner. It may take a sip of the honey, and when it gets its fill it will go toward the light at the point where the super-cover is slid backward. The chances are only one in a thousand that it will get back through the wire-cloth cones

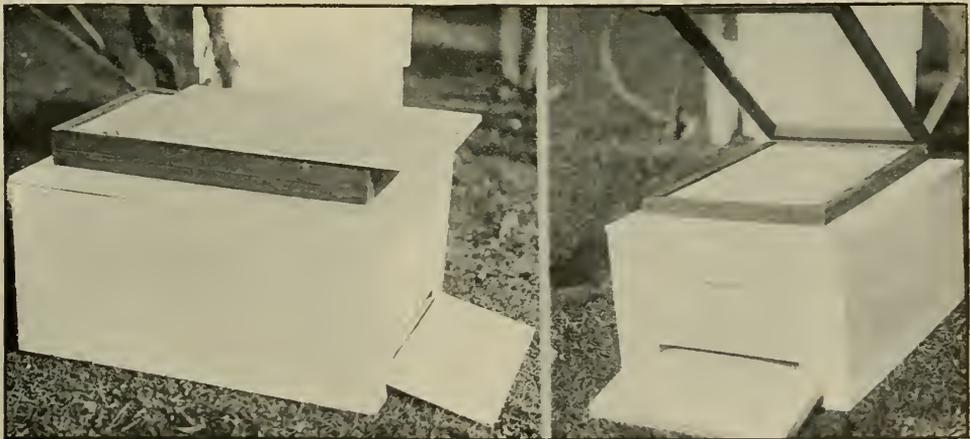

FIG. 2.—Outside detail of the robber-trap. A double screen is used, and honey is painted on the inner screen. Robbers are attracted by the odor of the honey. As they can not reach it from the outer screen they enter the hive and are trapped.

as mentioned, and it soon worries itself to death. Thus the trap works after it catches all the criminally inclined bees. The small amount of diluted honey on the inner wire cloth is used up, and automatically the robber-trap goes out of commission. The old sinners are all caught; and as there is no more honey to attract honest bees, Mr. Holtermann will see that none are caught.

In this way the few prowling robbers that may accumulate in two or three days are caught and automatically disposed of. They either starve or worry themselves to death.

Some years ago, when Mr. Wardell worked for us, it happened that one of his men left the door of the honey house open. That was in the days before we had robber-traps, and when robbers would be prowling about during the entire season. On this occasion the robbers rushed in pellmell. When the robbing was at its height Mr. Wardell came into the yard, and what did he do? He shut the door, then shortly after he went in and killed the whole mass of bees clustered on the screen. In explanation of his action he said we could not afford to have those bees go back to their hives and bring on an onslaught of hundreds and perhaps thousands of other bees. He thought it more economical for the Root Co to kill the first lot rather than to let them loose.

In pursuance of the same principle we later on devised robber-traps. They were first used by Mr. Pritchard at our north yard, and, later, put into commission at the home yard by Mr. Bain. They have been doing splendid service at both apiaries; and that their use is not wasteful of bees is shown by the fact that two gallons of bees will comprise all the robbers trapped in a whole season in an apiary of about 400 colonies and nuclei.

The question may arise right here, "Is the robber-trap of any use to the honey-producer?" Certainly not to the same extent that it is useful in a queen-rearing yard; but during a period of extracting, there are times when it appears to us it might be used to good advantage, especially if some careless employee should happen to leave the door of the honey-house open or allow a colony to be robbed to death.

As we have before pointed out, if robbers can be caught at the very start they will be found to be mainly from one hive, and a little later from two or three. If they get well going they will attract other bees by their uproar; but if robber-bees be floured, and

followed back to their hives, it will be seen that the great bulk of them go to only two or three hives. A yard man has to be exceedingly careless to allow robbing to get started throughout the entire yard.

### THE BEE-LOUSE.

A Pest Found in the South of Continental Europe and other Parts of the Orient.

BY MANUEL ARRUDA PONTES.

Dear Sir:—Enclosed you will find a package with 30 insects in a small box, and 3 bees in a small bottle, showing how these insects attack the poor bees. I don't know the name of this pest

Fenaes d'Luz, Azores.

[We will explain that we received this bottle of bees some time ago. On examination we found that these vermin are what is known as the bee louse (*Braula ceca*). The bees sent in alcohol could not be photographed, of course; but we attached one of the insects to the thorax of an ordinary Italian bee, as nearly as possible in the position of those fastened to the bees in the bottle. It is interesting to note, in this connection, that the long fine hairs on the thorax of the bee, which do not show, even in the enlarged photograph, prevented us from getting the *Braula* down close to the thorax. Of course, if the insect had been alive it could have "burrowed"

The bee-louse (*Braula ceca*) about to burrow into the fine hairs on the thorax of a bee, and suck the vitality—about four times actual size.

its way down through this mass of fine hair. We wish that all of our readers could see the original photograph, for, being enlarged, a mass of fine hair is shown all over the bee that is not visible on the bee itself except with the aid of a strong glass.

Prof. A. J. Cook, in "The Bee-keeper's Guide," describes this bee louse as a blind, spider-like parasite, which, considering the size of the bee on which it lives and from which it sucks its nourishment, is enormously large. He states that two or three, and sometimes as many as ten, are found on a single bee; but on the bees sent to us there was only one insect, and in each case it was clinging to the back of the thorax, about in the middle, as shown.

The bee-louse has done little damage, according to Prof. Cook except in the south of continental Europe, Cyprus, and other parts of the Orient. Our correspondent lives on an island in the North Atlantic, west of Spain.

Frank Benton, in a letter to Prof. Cook, as given on page 425 of "The Bee-keeper's Guide," says that the "*Braula*, or bee-louse, is no serious pest if the bees are properly cared for; although in old immovable-comb hives, where the combs are very black and thickened, and in case the queens are old, or where, through some extraneous cause, the colonies have become weak, these lice may be found on queens and workers alike. Mr. Benton thinks that, with the attention given bees in America, the *Braula* would never become a serious pest, even if introduced here.—ED.]

## A STRUGGLE WITH EUROPEAN FOUL BROOD.

The Removal of the Queen and the Introduction of a New Italian Queen Effected a Cure; Goldenes Preferred to Three-banded; the Alexander Method Followed.

BY EDGAR WILLIAMS.

Continued from Feb. 1st issue.

Arriving upon the scene I found smoke pouring up from the floor and about the windows; but there was no fire in sight. We rushed from the attic, then to the kitchen, when, behold, early that morning I had put the honey that I had extracted into a large kettle and set it on the kitchen stove to boil for a few hours in order that I might feed it back to the bees. Well, this honey had gotten the swarming fever. It was trying its best to swarm out of the kettle and cluster on the stove, while the smoke was making desperate efforts to pass through a small register in the ceiling up into the attic. The honey was taken off the stove, and the windows and doors opened to let out the smoke. But no sooner was this done than clouds of bees hovered around the outside, so that the doors and windows had to be shut again. The bees smelled the honey, so I left mother to suffocate with the smoke while I returned to the wax.

A few minutes had been spent with the wax when I received word that the bees were swarming. They had decided not to stay on those empty frames. Fortunately all my queens were clipped, and the bees were never returned. The day was a warm one; and by this time I was getting tired and somewhat nervous. I felt as though bees, wax, and honey were things I would rather not see during the rest of my life. Nevertheless, I wanted to finish the job that day and be through with it; so the rest of the combs were put in the kettle, allowed to steep awhile, and then taken out and buried in a manure-heap. I intended to press the wax from the combs; but bees were flying around some, and I was afraid they would get some of the honey. "Haste makes waste," and as a result I secured about 10 lbs. of wax from 300 combs. The slumgum might have been saved and the wax secured at another

melting; but just then it looked better to me in the manure heap. The frames were carried from the attic and dipped in the kettle of boiling water. That done, it was quitting time. I retired early that night very tired, almost sick, and mother was sick.

In the morning I was kept busy most of the time taking care of the swarms. Three-fourths of those thirty colonies were determined they would not stay on those empty frames. They would swarm out, return, and in a few minutes be in the air again. It had been nearly three days since I had shaken them. No honey was being gathered, and I noticed that bees were dropping from the cluster on to the bottom-boards. I began feeding back the honey, medicated with carbolic acid.

The next day being Sunday, I went to church. I returned to find that five or six swarms had come out and returned, nearly all the bees going into two or more of the hives. One swarm had come out so often I had caged the queen. The queen died, and the swarm came out without any queen. Entirely disgusted with the bees, the next morning I shook them on two combs. Now, these combs were perfectly free from disease, as they had been hanging in the top of the woodshed by wires for over a year. These were combs the bees had died on during the severe winter of 1903. The bees had shown no disease whatever the fall of that winter. Combs were clean, and free from honey. This was about six days after the bees had been shaken the first time. The combs that the bees had built since I fed them were melted, and this stopped the swarming fever. A few days afterward I noticed in front of one hive a drop of rotten matter, like that in the combs. Where it came from I can not say unless from the bees. Did this matter, as large as two peas, contain disease-germs? In a few more days I looked at the brood and found six diseased cells in four colonies. As the honey-flow came on at this time, the diseased cells all disappeared, and the bees built up rapidly; but during the drouth between clover and buckwheat the disease appeared again. Over half of the colonies showed disease. I gave up all hopes of getting rid of the disease by shaking.

I looked over my back numbers of GLEANINGS, and read in two instances of what was supposed to be pickled brood being cured by Italianizing. Like a drowning man grasping at the last straw, I immediately ordered fifteen Italian queens. The buckwheat flow came on, and the colonies all improved except six, which remained rotten with the disease, all through the fall flow, and had to be united when fall came. Two of these I sulphured. The following spring told the story. The fifteen colonies headed by Italian queens remained healthy, showing only a few diseased cells. The other colonies, scattered here and there among the Italians, were nearly all badly affected with the disease the same as the previous spring. This settled the question with me. I Italianized my bees,

and have had little trouble since, except with mismated queens.

There is quite a number of hybrid bees around me, and I find a mismated queen's bees, although raised from yellow stock, to have disease just as badly as the blacks. I managed to get rid of my mismated queens in the spring by uniting weak colonies with them, of course killing first the hybrid queen. I find the goldens better than the three banders. The latter show the disease somewhat. An occasional colony is to be found that will have it seriously enough so it will not store any surplus; but it is a rare thing to find a colony of goldens that has disease very badly. Some of them will show a few cells in a dearth of honey, but nothing serious. I find them just as hardy as the other. I have the Doolittle and the Alley strain.

I mentioned the fact that I sulphured two colonies. Well, I took those combs and hived my Italian swarms on them that summer, and they cleaned them up so that they remained healthy. I also took an Italian colony and shook it on to the brood of a diseased colony. About a third of the brood was dead with disease. That was during a dearth of honey, and in two weeks nearly all this brood was healthy. I believe the Italians are better housekeepers than the others. They clean the disease out as soon as a cell shows, and do not give it an opportunity to spread; while the hybrids and blacks will let it lie and rot, thereby infecting the adjoining cells.

Where one has the real yellow goldens the queens will sometimes mate with hybrid drones that are quite yellow, thus producing quite a yell 'w bee, having some black blood in it, and subject to disease. Mr. Lamson, a neighbor bee-keeper whose bees probably took the disease from mine, Italianized with the goldens, and his apiary is now nearly free from disease. Others have Italianized here the past summer. Mr Phillips, of Washington, D. C., visited my apiary twice. He pronounced the disease the regular European foul brood.

I bought a Carniolan queen, partly to test them with the disease. They also remained perfectly healthy. I change combs from one hive to another, no matter if they do show an occasional cell of disease, and feed any honey I want to. In fact, I manage the bees as if no disease existed. When I find a case of disease with considerable diseased brood I kill the queen, keep the queen cells cut out, and in ten days give to it a ripe queen-cell raised from one of my best golden breeders. This is only a modification of the Alexander plan. I do not wait quite as long, and am very particular to see that the queen is mated all right. If she is not, I expect to find another case of disease that fall or the following spring. My theory is this: The bees will clean out the diseased brood, and this will put a check on the disease for several weeks; and by this time brood from the young queen is hatching, and these bees, if the queen is purely mated, will free the combs from disease if it does begin again.

This spring I began the season with eighty colonies. Three of them were diseased, and had to be treated. Two were mismated queens, and one was a three-bander. Several others showed a few cells, but nothing serious. I did not do any thing with these except that I kept a record of the queens so that I would not be using them as breeders. I am also very careful about letting any thing but pure drones fly. However, most of mine are pure. I took 2000 lbs. of white comb and 1000 of extracted, and from the fall flow 2000 lbs. of comb and 1000 of extracted, or a total of 6000 lbs., and increased the 80 to 160 colonies. Some of the surrounding beemen have done better than this, as we have had a good season. I now keep the bees in two yards, and winter in the cellar. With the disease under control, and the wintering problem solved, I feel as if I were on the road to success, thanks to bee editors and bee-men who are willing to give to beginners their experience.

Pierpont, Ohio.

### ABSORBENT CUSHIONS VS. SEALED COVERS.

#### No Damp Cushions Found in Fifteen Years

BY A. E. JANSEN.

I can not imagine why any one should be troubled with dampness when using absorbent cushions. I have kept bees for fifteen years, always wintered out of doors, never with sealed covers, and have never had a damp cushion unless the water came through the roof, and have never lost more than one or two out of fifty or sixty hives, with one exception, and that was in the winter of 1903, when 95 per cent of all the bees in this county, not in cellars, died. I lost 10 out of 50 hives. In referring to my diary I find the bees did not have a fly from November 20 till Feb. 12. Sealed covers may be just as good; but why make a change when results can hardly be better? I use double-walled chaff hives of standard make, on stands made of 2x4 wood placed on the ground. The entrance is contracted to  $\frac{1}{4}$  or  $\frac{3}{8}$  inch; two sticks and a thin board are placed on the frames, partly covering them; a tray five inches deep is used to hold the cushion, which is packed with oat chaff so full that the telescope cover crowds it hard down on the frames, leaving no space between the cushion and the cover. The roof is thin, covered with tarred paper folded around the corners, and secured by a tin cap at each corner and at the sides. Our winters are very trying on hive covers. They must be absolutely water-proof to stand the soaking they get during long winter rains when covered with snow.

#### FALL UNITING.

U. S. Donis, p. 745, had trouble with uniting bees. For fall work, select a day late in November, when it is too cold for bees to fly, and when they are likely to be confined

to the hives for two or three days. Separate the frames to be moved in pairs beforehand, and set by the side of the hive where they are to go, so they can be handled quickly. The queen in the colony to which the united bees are to be added must be previously removed. If more than one queen is allowed in the hive, and the weather is warm enough for the cluster to break up, there will sometimes be trouble. A strong queenless colony can be united with a two-frame nucleus with a queen, and I have never had a failure. *Be sure the day is quite frosty.* The chill they get will not hurt them, but will cause them to cluster closer and unite quicker.

New Paltz, N. Y.

[We observe that you are using standard double-walled chaff hives and that the cushions are filled so full of oat chaff that the cover crowds it down hard on the frames, "leaving no space between the cushion and the cover." Practically all of those who report in favor of absorbing cushions, without a sealed cover between the cushions and the frames, have emphasized the *great importance* of leaving an air space between the cushion or packing material and the cover, so as to let the absorbents dry out. Assuming that moisture passes up through absorbing cushions, we are unable to understand how that moisture can escape when the cover comes in contact with the cushion, and is further protected by a tarred-felt cap over the whole. This moisture is bound to accumulate, and it seems very remarkable to us that your cushions should not be very damp before spring.—ED.]

### ABSORBENT CUSHIONS VS. SEALED COVERS.

#### Sealed Covers Not Entirely Sealed; Wheat Chaff Better than Oat.

BY W. H. KIRBY.

It is about twenty-five years since I started keeping bees, and from the start I adopted the system of wintering that I still follow—that of packing on summer stands in small open sheds, as per bottom illustration on p. 468 of the 1908 edition of the A B C and X Y Z which shows one of my sheds and my whole plan of packing with leaves, etc. With a seven-inch-deep telescopic cover, and under covers on top of brood-frames, a chaff box, the length and width of the hive, with a burlap bottom, is placed. These chaff boxes are four inches deep, and filled full of wheat chaff. No other kind is as good for the purpose. It remains open, and does not pack down close like oat chaff when a little damp. With the hives packed between and at the back with maple leaves, solid to the tops, the tops and fronts of the hives being without packing, they are exposed to the weather, and in low temperatures the moisture is

condensed on them, and inside the front end ice will form. This does no harm to the colony, as it melts and runs out of the entrances in mild spells of weather. The covers, having no ventilation, retain the heat of the colony, and the small amount of moisture that rises up through the chaff is attracted to the under side of the top of the cover, and a small portion of moisture settles on the top of the chaff. I have never yet seen any ice under the cover or on top of the chaff—only a mere dampness under the cover; and it was very seldom the top or only a part of the top of the chaff was wet much below a quarter of an inch.

In the spring, when taking off these chaff boxes I have found grains of wheat, that were left in the chaff, sprouted, and a growth of 4 inches made, thus showing that there was considerable heat in the chaff to cause this amount of germination.

One fall a number of years ago I had not enough chaff to go over all, there being some eight or ten hives that I put fine hard-wood sawdust on instead of chaff. This was practically the same as sealed covers. Every one of these colonies was injured, and most of them became extinct in the spring. They were attacked with dysentery, and outside combs were badly molded. This convinced me that fine sawdust is a failure for absorbents, and I have never used it since.

I think that if those who winter with cushions or chaff boxes on sealed covers were to examine closely, they would find some openings around near covers that allow upper ventilation and let the most of the moisture escape. Two years ago this month I bought a hive of bees from a neighbor who brought them in from the country. It had a single-board cover nailed on with a little crevice near one top corner. They had been out beside a strawstack without any protection. We brought them home one night when the mercury was a little below zero, and placed them in leaves. They wintered perfectly, notwithstanding this late cold disturbance. This experiment makes me think there must be some openings in these sealed covers to let off vapor.

As long as I keep bees I must have a deep telescopic cover, and wheat chaff and maple leaves for wintering. The last two or three winters I have tested some double-walled hives packed with leaves, and find them all right.

### NOT IN FAVOR OF HOLDING THE NATIONAL AT ANY FIXED PLACE YEAR AFTER YEAR.

BY J. W. R USE,

President of the Missouri Bee-keepers' Association.

The next best thing to attending a convention is getting a report of the sessions. When one attends the meetings he talks with many other bee-keepers and gets ideas that, of course, are not given in the reports. Then,

besides, there is the pleasure of meeting old acquaintances and making new ones.

I have the report before me of the Sioux City, Iowa, meeting; and among a great many other good things I notice, first, what President Hilton said when it was proposed to locate the meetings at some central place; also what Mr. Dadant said endorsing the president's views. I wish to voice my own sentiment in this matter. Mr. Hilton and Mr. Dadant thought that, to locate the meetings in one place, would deprive many of going on account of the distance to travel. Although it is very desirable to have as many as possible of those present that attend almost every year, many new ones are needed, so that there may be an exchange of views, methods, etc. Now, it is my opinion that, if all the meetings were held at one point, the death-knell of the Association would be sounded, and most of the bee-keepers in the United States would lose interest in both the meetings and in the Association.

The by-laws of the Missouri State Beekeepers' Association forbid holding a meeting in the same place twice in succession. Violating the by-laws has been suggested more than once; but I have always opposed doing so. While we have had meetings in some places that were unsolicited by any of the local bee-keepers, in almost every instance where we did this these local bee-keepers did not attend well.

Our best meetings have been held where the local bee-keepers were interested enough to give a pressing invitation and to attend all the sessions. We always have a rousing convention on such occasions. I am opposed to going anywhere without an invitation unless there is a special reason for doing so. There are many bee-keepers in my own county; but very few take any interest in attending a convention, and for this reason I would do my best against locating our State meeting at this place permanently. I believe in passing the appointments around.

Mexico, Mo.

## ARTIFICIAL SUBSTITUTES FOR POLLEN.

Can such Substitutes be Fed Inside the Hive During a Time when it is too Cold for Bees to Fly?

BY F. DUNDAS TODD.

If I am to judge from the reports that appeared in the various bee journals, the outstanding feature of the spring of 1909, so far as it concerned bee-keepers, was the marked dearth of pollen. I happened to be specially interested in the matter, and so noted carefully the various communications, being rather surprised to see that, over the whole continent, the one complaint was made. Some peculiarity of the seasonal conditions had in most localities prevented the development of the necessary fructifying material in the plants; but on Vancouver Island our situation was even more exasperating, for all

around us was a wealth of pollen in the willows; but the weather remained so persistently cool that the bees could not fly for weeks. The first loads were carried in Feb. 22, but from that date until April 3 there was scarcely a day warm enough for the bees to fly.

In my own case the situation was a highly critical one. In September I had fed the bees until every hive contained at least 25 pounds of actual weight in stores. Colonies have been known to go through the winter here on 12 pounds; so I felt every thing was safe and sound. After a zero wave early in January I was astounded to find one-third of the colonies dead of starvation, while the others were on the verge. Now, pollen had been carried in freely all the fall; but in the dead hives there was not a scrap, and mighty little in the others. Candy was at once given above the frames; but what to do in the matter of giving a substitute for pollen was the crucial problem. As a matter of fact I did nothing, for the very good reason I did not know what to do.

The plan of giving flour out of doors I was familiar with theoretically; but since the temperature was too cold for the bees to fly this method was entirely unavailable. So all I could do was to hope for the best, and watch one colony after another gradually fade away of what is generally called "spring dwindling," but which one writer recently labeled "pollen-dearth." When the weather did get warm enough for the bees to fly I found myself owner of only one-third the number of colonies that had been put away for the winter, all weak ones at that.

Naturally there arises the problem, "Is there a practicable method of giving a substitute for pollen in the hives?" All through February and March I searched bee literature in vain for light on this subject, but it was not until fall that I got track of any thing that looked feasible. When the season's work was over I decided to read carefully every book in my possession, just to see that I had not missed some useful hint that was not considered by the authors to be of sufficient importance to be indexed, and soon I stumbled over one sentence that was suggestive but not at all explicit.

"The Book of Bee-keeping" is a Chicago reprint from plates of what is apparently an edition originally published in England. At the end of a paragraph on spring feeding I found this sentence: "Flour candy can be given with advantage at this season of the year;" not a word anywhere as to how it should be made, whether the flour should be added at the beginning of the cooking, the middle, or the end. So the only interpretation possible is this: Artificial pollen in the form of flour can be given provided it is mixed in the syrup of which the candy is made.

The search had now become interesting, so all American bee books were gone through page by page, and at last I was rewarded by finding a few sentences on the subject in Mrs. Comstock's "How to Keep Bees." On

page 142 she says, "The unbolted rye flour, or even oatmeal, or whole-wheat flour, may be used by the bees as a substitute with perfect success. *The meal may be mixed with the candy if it is desirable.*" Now, this is explicit; but I should much like it if some details as to methods of cooking had been included.

"A Modern Bee-farm," by Simmins, is a book I like to read in the winter time to wrestle with his startling ideas and devices, trying to dig the essentials out of his rather involved language. Recently I found he also has something to say on the flour-candy proposition—just four words, and then he leaves it in peace. Let me quote the whole paragraph, beginning on page 189 of the 1904 edition:

The act of breeding, which recommences, in normal colonies, about mid-winter at the center of the cluster, is not in itself a disturbing influence, for as yet its extent is never developed beyond the means at hand for its moderate continuance. But when the owner begins unduly to feed candy, and meal added thereto, then the elements of additional unnecessary excitement are immediately apparent in a large death-rate caused by the premature flight of the workers in search of large quantities of water. The cluster expands unnaturally, and thereafter a serious drain is made upon the vitality of the bees in keeping up a higher temperature generally.

There the proposition rests, so far as I am concerned, for I am unable to find any more references in the bee literature at my disposal. But I am intensely interested in this method of giving the bees a substitute for pollen, if it is practicable, for the indications are that this part of the world may have a repetition of the seasonal conditions of last spring. This is written exactly one year from the day when the abnormal zero wave struck us; but there are no signs of its being repeated. Instead we are having steady cool weather, the thermometer hanging around the freezing-point, and have had since the end of November. My bees are wintering on about 16 pounds of honey-dew and 11 pounds of syrup, so the prospect is not altogether cheerful, seeing that they have not had a flight for over a month at the date of writing, and may be confined three weeks more at least. In most winters here I am assured there are many flight days each month, but this one is different.

Victoria, B. C., January 4, 1910.

[It is unfortunate for you that you did not have at your command the back volumes of this journal, particularly for the years from 1877 up to 1884 and 1885. During that time there was considerable discussion on the subject of giving bees what was then called "flour candy." This is made by mixing one part of rye meal with three parts of white sugar, and wetting it down with a little water. It is then placed over a slow fire and cooked until it is ready to "sugar off." This point can be determined by dipping the finger in cool water, then into the kettle of candy, and immediately back into the water. When the film of syrup breaks like eggshells from the end of the finger the candy is just right.

It is now taken off the stove; and as soon

as it begins to harden on the sides of the kettle the mixture is given a good stirring, the stirring being kept up until the candy is so thick that it can just be poured. Greased tin pans should be in readiness, when the contents of the kettle are poured into the pans and allowed to cool. Cakes of this candy are laid on the brood-frames in the spring, or about the time when brood-rearing will permit. Such candy will supply the bees with syrup as well as a farinaceous diet, so they will rear brood.

The question is raised right here, "Why is there so little said about this kind of candy now? Why should not full directions be incorporated in our text-books of to day?" In the first place, a flour candy, such as is described, is very difficult to make. Even a confectioner has to try several batches before succeeding. In the second place, the meal or flour in the candy is quite likely to stimulate brood-rearing *out of season*; and brood out of season that chills and dies by subsequent cold weather puts a severe drain on the colony, if it does not kill it outright. For that reason it seemed best generally speaking, to let nature handle the problem of a farinaceous diet for the bees. Ordinarily, brood-rearing should not commence much before natural pollen can be gathered. There is only an occasional season like that of 1909, when bees really suffer from a want of nitrogenous food. It is during such seasons that a meal or flour candy in the hive would be worth every thing to the bee-keeper; but even then it would be far better to place dry rye meal on trays outdoors and let the bees themselves gather it and carry it to their hives. It is much safer for the beginner to furnish rye meal in this way than to give it in the hives. The bees can not, of course, gather this rye meal before they can use it to advantage, and right here is the reason why we recommend meal outdoors instead of meal candy in the hive. If, on the other hand, the meal be given in the hive they are almost sure to begin brood-rearing whether conditions are suitable or not outside. For that reason we dropped all reference to flour candy from our A B C of Bee Culture, because we found that beginners were inclined to *overdo it*; and some, strangely, would give it during midwinter just when it would cause dysentery. There is no doubt that flour candy could have been given in many yards last spring to very good advantage. The weather happened to be warm enough for bees to rear brood, but too inclement for them to fly very much; and when they could fly, there was no natural pollen. If meal had been given in the hive with the candy, there is no doubt that a large amount of brood would have been saved last spring. As it was, dead brood from all over the country was sent to this office, he senders inquiring whether the brood died from disease. In almost every case a diagnosis showed that the brood probably died from a want of the nitrogenous element in their food. After natural pollen was supplied brood ceased dying.—ED.]

## HONEY FOR COOKING.

### An Experiment in Making Doughnuts with Different Amounts of Honey and Sugar.

BY EMMA M. WILSON.

After reading what was said about honey doughnuts, p 34, Jan. 1, I concluded it might be a good plan to try to see what could be done. I made three different batches, and am sending you samples of each. Batch No. 1 was made after this recipe: One cup hot mashed potato; 2 tablespoonfuls of shortening; 1 egg;  $\frac{1}{2}$  cup honey;  $\frac{1}{2}$  cup sugar; 2 teaspoonfuls baking-powder; 1 saltspoon of salt;  $\frac{1}{2}$  cup sweet milk; a little nutmeg.

Make a cream of potato, shortening, honey, sugar, and beaten yolk of an egg; then add the milk, nutmeg, and salt; lastly, add the flour, in which the baking-powder has been sifted, and the white of the egg beaten stiff.

It is hard to tell exactly how much flour was used; but don't mix it very stiff at first; then try frying a small piece of dough; and if not enough flour, add a little more until they are just right.

Batch No. 2 was made exactly like No. 1, with the exception that one cup of honey was used and no sugar.

Batch No. 3 was the same as No. 1, with this difference: One cup each of honey and sugar was used instead of  $\frac{1}{2}$  of each, and two eggs instead of one.

Now, when I came to fry them I found this difficulty. I did not dare to keep the lard nearly as hot as when frying doughnuts without honey. They browned very quickly, and would get too brown before they were cooked through if the lard was kept very hot. So I rolled them out thinner than usual, which helped. None of them were more than  $\frac{1}{2}$  inch thick before frying, and most of them less.

Now as to how these three different batches were liked at our home

The first batch, we all agreed, were good; but Dr. Miller and myself thought they might be improved by being just a little sweeter. Mrs Miller thought not. She has not quite as sweet a tooth as we have.

Dr. Miller wanted some made entirely of honey, hence the second batch.

Mrs. Miller and I do not like them as well as batch No. 1, and Dr. Miller thinks them better. Perhaps there may be some prejudice in the case, because they are made of honey.

Batch No. 3 — too sweet for Mrs. Miller. Dr. Miller and I think they are pretty good.

As to the keeping qualities of these doughnuts, I can say nothing as yet, as they were baked only yesterday, Jan 17. I should expect those made with all honey to keep best.

Now, Mr. Editor, I am really very sorry for your digestion if you have to sample all the doughnuts that are launched upon you; but please remember that you invited the catastrophe.

Marengo, Ill.

[Our own judgment in regard to these doughnuts is practically the same as yours. No 1 seems to have the best flavor. No. 2, which is all honey, is much more moist, but the flavor of honey is a little too pronounced, although some might like it for that very reason. No. 3, having a large amount of honey and sugar both, is too rich; and besides, the doughnut is comparatively dry and hard. We have been making some experiments here, and it appears that a moderate amount of honey and no sugar makes a softer cake, and gives a flavor that is pleasing.

We wish to suggest that you put away a few of each kind and keep them for a month, and then test them for their softness and moisture. We should like it if you could report to us again after, say, sixty or ninety days.

Apparently an excess of sugar and honey makes the cake too dry and hard after it begins to age. Honey used alone for sweetening surely makes a softer cake. Some of the very best doughnuts we have eaten were very soft but only very mildly sweet. We have not much of a "sweet tooth." and perhaps this is why we like the smaller amount of sweetening.

The honey flavor in the doughnuts seems to be that of some fall honey, and we should like to inquire whether you have ever used a mild honey like clover in making doughnuts. Alfalfa honey is fine for cooking, for it does not have a strong flavor, and the suggestion of mint or cinnamon is quite pleasing.—ED.]

### DO BEES FLY IN A STRAIGHT LINE AFTER NECTAR? ARE THEY ATTRACTED BY SCENT OR SIGHT?

#### Golden Italians Not Hardy.

BY RALEIGH THOMPSON.

I have made some close observations in the last two years. My apiary is in a valley half a mile wide, with hills all around except on the west, where the unbroken country extends for miles. I have traced my bees in this direction four miles. I knew they were my bees for they were goldens, and the first that were brought to this part of the State. I will say right here, however, that I did not keep the goldens long, as they were not hardy, and were too much inclined to rob. There is no strain of bees that goes ahead of the leather-colored Italians.

There is a very narrow valley running east for about two miles. My apiary is south of this about 300 yards, and is situated at the foot of a hill with a narrow opening into the valley on the north. Now my bees go north through this opening, then turn east and follow this valley along the south side and the sumac on the hills at the upper end—that is, at the east end. The valley is very irregular in outline, and I have watched my bees follow this route for hours. The hills are covered with timber.

Like many others I thought bees found nectar by sight; but I believe now they find it by scent. Last summer there were about thirty acres of alsike  $2\frac{1}{2}$  miles northwest of my apiary. There was very little clover nearer, and the first ten days that this clover was in bloom the wind was blowing from the east. The bees were storing some from sources around home, but not a bee was going to the thirty acres. I was becoming discouraged for I had supposed that bees would go to that alsike clover. One morning, however, as I was coming from the barn I heard an uproar and thought the bees were swarming. I ran out, and it seemed as though all the bees were leaving the hives. They were going to that alsike clover, the wind having changed so that it blew from that thirty-acre field. The suns filled up rapidly. All the bees had to fly over timber almost all the way to get to this clover, and hence I am convinced that they find nectar by scent rather than by sight.

Oakwood, Ind.

[This confirms to a great extent some observations which we made while at the Alexander apiary, located, as it is, upon a side hill, commanding a view of a valley where the eye can take in a panorama miles distant. We have been under the impression that bees depend largely on a telescopic vision to determine the exact location of any flora that might have honey; and while this may be true our correspondent has introduced pretty strong proof showing that they are also guided (sometimes at least) by scent. This is very interesting, and we shall be pleased to know whether others have observed the same thing.—Ed.]

---

### THE ALEXANDER PLAN OF CURING EUROPEAN FOUL BROOD.

**Even if it is a Success, is it Ahead of the McEvoy Method from the Standpoint of Economy? the Alexander Plan Means that a Colony Must Dwindle Forty five Days.**

BY E. M. GIBSON.

I fail to see any thing but loss in the Alexander plan of treating foul brood of either the European or American type. I am well aware that it would be futile to gainsay any thing which that grand old man of Marengo might endorse (page 760, Dec. 15), but I do not think the Alexander plan has the stamp of his unqualified endorsement as yet, and so we may give our reasons for doubting, and let the readers be the judges.

With the above-mentioned method the queen is taken away from the diseased colony until the brood is all hatched, which takes 21 days (I have my doubts as to whether this is long enough in all cases of European; certainly it is not for the American kind). Well, 21 days are gone without a laying queen in the hive at best. One is now in-

duced that is supposed to be laying; but if a virgin she does not lay until the 21 days have passed. There is no laying queen, then, until the expiration of 24 days; for, even if a laying queen is introduced, it will be three days before she lays. Now it will be 21 days more before any brood is hatched, making a total of 45, and by this time the colony is much reduced in numbers of bees, and little or nothing can be expected of it in the way of surplus for the season.

What is to be done with the queens taken away from the diseased colonies? No one but a queen-breeder would be likely to have nuclei enough to accommodate them; and to prepare nuclei not only takes time, but means a further loss of bees and brood. Then there are two queens to hunt for—one in the diseased colony and one in the hive from which the brood is taken, for fear of getting the queen also.

Let us analyze the McEvoy plan, on the other hand, modified by using full sheets of foundation to start with—a plan which has been successful in my case, and which has led me to believe that the use of starters is superfluous if one is careful in other ways. One might use starters and be careless in some other way which would prove more disastrous. With the modified McEvoy treatment we do not have to find the queen. It is not necessary to start nuclei to hold surplus queens, and no colonies need be robbed of brood and bees. With one helper I can transfer a colony on to foundation every ten minutes, and keep up this rate for eight or ten hours a day. One would have to be extremely successful to find 48 to 60 queens in one day (I am making these comparisons of time, etc., as I write). In three days after a colony has been brushed on to the foundation, combs will have been built, and eggs laid in them; and from that time on, the queen will have all the room that she can possibly use, so that in 24 days from the time the colony is treated there is hatching brood in as good a set of combs as were taken away, all being filled with brood. In the Alexander plan the queen in the same time will have just commenced to lay, and 21 days must yet elapse before any brood hatches to strengthen the colony.

The only difference between the McEvoy treatment and the plan of shaking bees on to foundation to make them carry honey into the super is the brood that is given back to the bees after it is hatched. I know by experience that a colony brushed on to foundation, as soon as the bees begin to build freely in the spring will be only one extracting behind those which are not so treated, providing the disease has not depleted them too much, and they have a vigorous queen.

If there is sufficient honey in the diseased combs that were removed to be worth while, it can be extracted, boiled, and fed back after being diluted, and, if one cares to go to the trouble of utilizing the brood to start new colonies, this can be done by piling up the combs six or seven bodies high and letting the brood hatch, then putting all the

bees into a single hive, giving them a set of frames filled with foundation and a laying queen. I followed this plan with a part of my diseased combs, but abandoned it, as the process was too slow. It is my opinion that the few colonies which we may get in this way hardly pay, for the work is nearly doubled, and the diseased combs are left around too long. I have always felt that the sooner they are gotten rid of the better. The wax from a full set of combs will go a long way toward making foundation to refill the frames. Now add the set of combs made by the colony treated and we are ahead of the Alexander plan (not counting the diseased honey), by the amount of wax from the combs and by two-thirds of a crop of honey, at least; for a colony that has been 45 days without hatching brood in the height of the honey-flow can not be expected to produce any surplus; and if the bees gather even enough for their own consumption they will do well.

As to what we get for our time of melting up the diseased combs, making foundation, and refilling the frames, I can say that the treatment of either kind of foul brood can be done successfully only during the honey-flow, and it is hardly necessary to ask how much 21 days in the height of the honey-flow is worth. We think any one would be willing to do the work above mentioned for even one-half the honey that is produced in that time.

#### CONDITIONS DIFFERENT AT THE ALEXANDER YARD.

It must be remembered that conditions were very different with Mr. Alexander than with most of us. As I understand it, all of his surplus was derived from buckwheat, the bees building up on the earlier flowers, so that he had the whole summer in which to manipulate the bees in settled weather. Under these circumstances a queen could be removed from the hive for 21 days, and there would still be plenty of time for the colony to build up for the main honey-flow. Many of the things which Mr. Alexander advocated can not be successfully followed, for this same reason. I have in mind dividing, putting weak colonies above stronger ones, etc. I have twice tried his method of dividing by putting brood on above and setting the super off after ten days, and it is a complete failure here, for the weather is too changeable. The weather may be all right when the work is done; but before the ten days is up, a cold spell may come, the queen-cells will be torn down, and started over again in a few days with brood that is too old. Any one who practices this plan long, where these same conditions exist, will soon have a lot of worthless queens. Then in the case of putting weak colonies above strong ones until they are stronger, if it happens to turn cold the bees will all leave the small colony and go down with the larger one below where it is warmer, leaving the queen above to freeze. It is better to double two or three of the smaller colonies and give them less space to keep warm. I can see how all of these plans

may be successful after the weather becomes settled and the time for sudden changes is past. In this section bees have a long time to build up—from February to June; but this is during the rainy season when the weather is unsettled and conditions are very similar to the spring months in the East.  
Jamul, Cal.

[Mr. E. M. Gibson, it will be remembered, is the correspondent in California who has written such excellent articles during the last year or so. His complete analysis of the two methods of cure, the McEvoy and the Alexander, should be carefully read by all those who are interested in this great question of ridding the country of brood diseases. It is most certainly true that the question of locality must be given careful consideration. In this connection we recall that more than one of our subscribers were not able to work some of the methods advocated by Mr. Alexander, and this was due to difference in conditions.]

Referring to the Alexander cure, it is possible that this could be applied to good advantage after the white-clover flow, when there would be a period of comparatively little brood-rearing. In most localities in the Northern States after the middle of July, when clover and basswood are out of bloom, there will be practically nothing doing for the bees for a month. Now, it would be possible that the Alexander method of cure might be applied at such times to the entire yard without great loss, and feeding afterward. On the other hand, when a honey-flow is on, or, we will say, during the spring when brood-rearing should be carried on to its limit, it would seem that the Alexander plan would be expensive and wasteful, and that at such times the McEvoy method should be employed instead.

The last time we visited Mr. Alexander we talked over the McEvoy and the Alexander plan of cure. If we remember correctly, he made the statement that the McEvoy plan failed to rid his apiary of the disease; that it was only after he employed his dequeening method that relief came. He then went on to mention yard after yard of some of the most successful bee-keepers in New York who had been using the McEvoy treatment, and how, in spite of all their efforts, the plague was continually coming back. In later years, however, the McEvoy plan as now administered seems to be giving good results, for, as we understand it, both European and American foul brood are well under control. As the McEvoy plan has been used almost exclusively, this condition of affairs is brought about by that particular plan of treatment.

We are still desirous of securing further reports on this general subject. In the meantime it would seem that we must take carefully into consideration the question of locality and general conditions. There are probably times when a combination of the two methods can be employed to very good advantage.—ED.]

## HEADS OF GRAIN FROM DIFFERENT FIELDS

OUTDOOR-WINTERED COLONIES LOSING A COUPLE OF DOZEN OF BEES DAILY; IS IT AN ABNORMAL CONDITION?

I have my bees outdoors in a good tight outside case; 8 single-story hives about four inches apart packed with straw between hives; also behind and on top. Each hive has an entrance 3 inches by  $\frac{3}{8}$ , with a storm-door leaned up in front to keep out sunlight, storms, and wind. I notice every day 20 or 25 bees from certain hives, and four or five bees from others, come out and die on the alighting-board, the weather nearly down to zero. Can you say if this condition is right, or are they too warm? Should the entrance be enlarged to six or eight inches? It seems to me that at this rate of coming out there will be few if any left by spring.

Ruscomb, Ont., Jan. 13.

C. A. YORK.

[No matter how well bees are packed outdoors, there will be a certain mortality taking place daily. Some bees, because of bad food, venture from the cluster; others, from other causes, become chilled, then starve and die. Others still, because of old age, also drop off. Four or five dead bees daily is not a great loss, if you stop to figure it up, and is not much larger than we have had at Medina, and what we have observed at other yards where bees are wintered outdoors. They may not appear at the entrance every day; but on certain days when it warms up there will be a sort of house-cleaning in which there will be quite a number of bees pushed out, and one would think that a large number were dying. The probabilities are you have an average of at least ten thousand bees in each of your hives. Suppose there is a maximum daily mortality of 25 bees. There are about sixty days, possibly, of cold weather. This would make only 1500 bees, or a total of fifteen per cent of the survivals. The stronger the colony the larger the number of bees that will die daily, but the smaller the percentage of loss.]

The number of bees found dead at the entrance will be much greater *this winter* than usual on account of honey-dew. If you have no honey-dew your daily percentage of loss should be smaller.

But the death loss outdoors is usually no greater (if as large) than the loss inside of a good cellar. We have stepped in many a cellar and found anywhere from one to two inches of dead bees on the floor, and yet out of that same cellar would come a lot of strong healthy colonies for spring. It has been contended that many of these bees are superannuated, and would die any way. It is our opinion, based on our own experience, that a two-inch deep loss of bees all over the cellar bottom is too great. We have wintered in our shop cellar, and the total number on the cellar bottom—well, they could almost be counted.

But perhaps some who were wintering outdoors will report that they see no dead bees in front of the entrances of their hives. The first warm day the bees can fly in the spring there will be found quite a large bunch of them in front of the entrance of almost every colony, if there is very much honey-dew in the hive. These would be the bees that died all during the winter.

Right here ought to be entered a caution. Sometimes the dead bees will clog up the entrance, and then there is sure to be trouble; because a closed entrance usually means death to the whole colony.

Replying to your question, your entrances are large enough *providing they are kept clear of dead bees*. If you do not make a practice of raking them out clean about once a month, the entrance had better be 8x $\frac{3}{8}$  in the case of a strong colony.—ED.]

CARBOLIC ACID IN SPRAYING-SOLUTIONS TO PREVENT BEES FROM BEING POISONED.

Mr. Root.—I was pleased to receive your letter of the 15th, inclosing one from Messrs. Metcalfe & Parks, of Mesilla Park, N. M., who, I remember, reported to you last year that their bees had been poisoned by arsenical sprays on fruit-blossoms. In reply to your inquiry as to whether carbolic acid can be used in dilute solution in the spray liquid to repel the bees and at the same time not injure the setting of the fruit, I will say that I think this is possible. I must immediately confess that I have had no practical experience in this matter, nor do I know any one else who has had such. My recommendation would be that the trees be spray-

ed just after the blossoms drop. They are not then secreting nectar, and the bees would not be working on them. The results of spraying would be fully as good as or better than if the liquid be applied while the trees are in bloom. From a horticultural standpoint I surely do not think it best to spray trees with any thing while they are in bloom. Thus the danger of killing the bees will be entirely overcome.

As the inquirer does not state what kinds of fruits he sprayed I can not give the formula with such certainty as I would if I knew for sure whether they are the pome fruits or the stone fruits. In general, however, 2 lbs. of arsenate of lead, 1 lb of bluestone, and 3 lbs. of lime in 50 gallons of water will be found safe and efficient. If there really be danger of the bees sipping this, it can be avoided by the addition of a very small quantity of carbolic acid. The crude article will do as well as the refined, and is, of course, much less expensive. By shaving 1 lb. of hard soap fine, in a gallon of hot water, one can add one gallon of carbolic acid to this soap solution, and emulsify it by vigorous beating or churning through a spray-pump. It will become a creamy mass, and can be kept as a stock solution. Only enough of this will be needed in each barrel or tank of the arsenical spray to repel the bees; and as bees are very readily repelled by the odor of carbolic acid, this means that the quantity will be so slight as not to prove injurious to young fruits. It is my opinion that the addition of one-tenth of one per cent of the carbolic acid would pollute the spray liquid so as to repel the bees, and that considerably more than one per cent will be needed to injure the fruits.

Harrisburg, Pa., Jan. 13.

H. A. SURFACE,  
Economic Zoologist.

[Reference has been made before in these columns to the use of carbolic acid in spraying-solutions to keep the bees away from the fruit-trees; but no one so far seems to have any definite knowledge of how the acid has been used. If any one can furnish the information we shall be glad to hear from him. In the meantime we have no doubt that the suggestions made by Professor Surface (who is probably one of the best authorities in the United States on spraying) will be safe to follow.—ED.]

KEEPING WEEDS DOWN AROUND HIVES.

How can I prevent grass and weeds from growing about my hives? For some time I have had my ashes put in the apiary in order to keep down grass and weeds, and to give the place a neat appearance; but this season dandelions, docks, and fall grass are most luxuriant; and even salt does not kill them as I once thought it would. Kindly tell me something not poisonous to bees that will surely keep down all growth around the hives.

Moorestown, N. J., Aug. 7.

S. E. WILLIAMS.

[If you have a permanent location for your apiary, and wish to go to the expense, a good way is to make a concrete foundation for the hives. This can be made a few inches larger than the hive in order to prevent grass and weeds from growing too close. The top of this foundation may be made level with the ground; and since there would be no object in using a very thin mixture of concrete we believe that one part of cement to nine or ten parts of sand and gravel would be sufficient. If the sand and gravel can be obtained cheaply, the expense will thus not be very great aside from the labor of making them.]

Salt will kill weeds and grasses if *enough* is used. It is so cheap that small handfuls of it scattered here and there, especially around the entrances of the hives, will make short work of vegetation not wanted. If your yard is located out in the country where sheep are kept, you can easily crop down grass and weeds by letting the sheep loose in the bee-yard at night. In fact, it will do no harm to leave them there all day. Occasionally a sheep will get close to an entrance; but unless a bee stings it around the eyes or nose it can do but very little harm. It does not take a sheep long to learn to push its head under a clump of bushes, when the rest of its anatomy will be taken care of by its wool.—ED.]

MOVING BEES IN COLD WEATHER; IS SNOW A PROTECTION TO OUTDOOR-WINTERED BEES?

What, in your judgment, would be best for me, as I do not find any thing printed regarding my situation? I have bought 60 colonies of bees 20 miles distant; expected them to have sufficient stores to remain where they are outside; but by chance I discovered they were very light. We have a solid sheet of snow from one to three feet deep all over. Would you advise me to move them home those 20 miles on sleighs when we

get a temperature of from 30 to 40°, and place them in a bee-cellar where I already have 70 colonies? Would you expect it to cause a great loss owing to bees filling themselves or would it not be just as bad in early spring when roads are rough, owing to the greater activity of bees at that time?

I have another yard of 60 colonies snowed half under before I could get them in the cellar. They are in ordinary dovetailed hives, Colorado covers, so I left them, thinking the snow was as good as any protection to bees. Would you put them in the cellar the last two months, as I now have a cellar empty ready for bees?  
NEILS A. NELSON.

Dike, Iowa, Jan. 18.

[It is perfectly feasible to move bees during cold weather when sleighing is good, although we would select a time when it is just below freezing. We would not advise waiting until spring when the roads are broken up. If they be moved now and put into a cellar the disturbance would cause no trouble—at least, reports where precisely this same thing has been done in the past have not shown any bad results.

Yes, snow, if banked up around the hives, is a decided protection. The more we can have the better, providing it does not melt around the entrance and freeze, sealing the entrance hermetically. That is the only danger arising from too much snow. An ordinary light snow banked up around the entrance will do no harm; but should there come a thaw, then a severe freeze-up afterward, the apiarist would do well to look to his entrances.—ED.]

**CAN THE DOOLITTLE PLAN OF NON-SWARMING BE WORKED WITH THE CHAFF HIVE? FEEDING BEES WITH A SYRUP MADE FROM SCRAPS OF CANDY.**

Will you please inform me how to work the Doolittle plan of non-swarming? I have all double-walled hives with tight bottoms. Could I put a single-walled hive on top? Can I shake No. 2 hive into No. 1 instead of No. 1 into No. 2?

I also should like your opinion of feeding scraps of candy to bees in the spring in syrup form, such as horehound, anise, tartaric acid, menthol, peppermint, butter-scotch, leaving out medicated cough drops, burnt sugar, etc.  
PHILIP F. DEBBOLD.

Clinton, N. Y., Jan. 19.

[There is no reason why you should not work the Doolittle system of non-swarming with a double-walled chaff hive, providing such hive is built on the modern plan, so that a single-walled hive or super can be set on top. If you consult the bee-supply catalogs you will find in most cases that single-walled supers and hive-bodies can be used on top of double-walled chaff hives of the same frame capacity.

We would not advise you to give bees syrup made from scrap candy during cold weather. You can use this to good advantage toward spring when the bees will have a little opportunity for a cleansing flight. As a general thing we would not recommend any thing for winter food except the best of honey or granulated-sugar syrup.

Burnt sugar would be almost sure death to a colony, although it could be used safely enough in warm weather when the bees can fly.—ED.]

**BEES GETTING CHILLED AT THE ENTRANCES OF THE HIVES.**

I started bee-keeping in the spring of 1908 with one colony. I increased this colony to four fairly strong colonies, which are provided with good stores, and are in single-walled hives, packed warmly in winter cases. The bees wintered well last winter; but this winter, although the conditions are the same, I find a handful of dead bees every few days around the entrances, both outside and inside. They seem to run to the entrance and get chilled so that they are unable to get back. Is the hive too warm or too cold? We have had zero weather lately, and I had the entrances  $\frac{3}{8}$  x 2 inches, but have lengthened them to 6 inches and in some cases to 8; but the bees come out and die just the same. If this keeps on I shall lose all before spring, as a handful every other day is too much loss for any colony.  
P. J. HOEVEL.

Bradentown, Pa.

[Mortality of bees is greater during severely cold winters than mild ones. This is one reason why you find more dead bees in front of the entrances this winter than last; but probably the greatest reason for making the bees come out is the character of the food. If there is much honey-dew in your hives many bees will become uneasy on account of their intestines be-

coming clogged. Those bees you see coming out are probably seeking a chance to fly. They chill and die when they come outside. Bad food is one of the causes that induce spring dwindling.—ED.]

**NEW MEXICO WELL ADAPTED TO BEE-KEEPING.**

As I have not seen any thing from our country, I venture to report. I live in the northwest corner of New Mexico, in what is known as "The Sunny San Juan Co." This is a great fruit country—one of the best in the West. It is a new country, with a delightful climate, and one of the very best for bees.

I have been in the bee business for a number of years, and I have made it my leading business. I can say that, so far, I have never made a failure. Failures do come, but I have been so fortunate as to escape.

I started with bees in this place one year ago by purchasing 140 colonies. Of these I lost 35 in the spring; and as I had to feed, things looked discouraging; but the willows began to bloom, the bees took courage, and we got a good honey-flow. Afterward the swarms came till I now have 170 colonies.

I had a large swarm July 4 that filled the hive and made me seven 24-section cases of honey that sold at home at \$2 75 a case.

I have kept a strict book account, and I find that an investment of \$528 for bees and all supplies has brought a return of \$895 in twelve months, and I now have more bees and supplies on hand than I started with.

I did equally well when in Colorado; but I think this the best country for bees that I have seen yet. I have been in a number of States.

REV. T. D. SAFFELL.

Farmington, New Mex., Dec. 20.

**HOW TO MAKE SYRUP SO THAT IT WILL NOT CANDY.**

Several years ago my father kept bees at Quincy, Michigan, and one winter he was obliged to feed his bees quite a little syrup. He experienced some difficulty with the first he made in keeping it from candying. He was a subscriber to GLEANINGS at that time; and as I remember it he wrote you to learn how to make the syrup properly. I do not keep bees, but have occasion to make syrup from granulated sugar frequently, but have not been successful in making it so it will not candy. The syrup we make we prefer to have quite heavy.  
E. D. RICKETSON.

Mason City, Iowa, Jan. 19.

[Our practice is to put nothing in the syrup to prevent candying; but there are some who find it necessary, especially if the syrup is thick, say two 2½ parts of sugar to one of water. To prevent candying, Dr. Miller recommends a teaspoonful of tartaric acid to every 20 pounds of sugar. Doolittle uses honey in place of acid in these proportions: 15 lbs. of water, 30 lbs. of sugar, a day after the mixture has been thoroughly heated he adds 5 lbs. of extracted honey, making in all 50 lbs. of feed.—ED.]

**IS THERE ANY LAW REGULATING THE DISTANCE OF BEES FROM THE HIGHWAY?**

Will you please inform me if there is any law as to how far bees may be set from the hives of our neighbors—also from the street?  
WM. H. MORSE.

North Girard, Pa., Jan. 19.

[There is no law in any of the States that we know of that regulates the distance that bees shall be kept from the general highway. As a matter of precaution, however, we would advise putting all bees in the back end of a town lot, or, if they are to be located in the country, at least 100 feet from the general highway, and the same distance from the line fence, especially if there is a cultivated field in which horses may be driven in plowing or cultivating.—ED.]

**A SUCCESSFUL WAY OF KILLING RATS.**

There are many ways to catch rats; but most traps are useless so far as getting the "old timers" is concerned. An experiment of mine has proved successful with both the old and the young rats. I take two tin pans; fill one with meal and dry plaster of Paris, half and half, well mixed together, and the other one with cold water. I put them where the rats can get to them easily, and then watch if possible. The rats eat the meal and then drink the cold water. The plaster causes them to drink a good deal of water, which sets the plaster and causes death. I have found rat-awards almost as hard as a stone.  
W. HACKING.

Idaho Falls, Idaho.

[This looks as if it might work well. If any reader tries it we should like to have him report.—ED.]

# OUR HOMES

By A. I. Root

Thou art the Christ, the Son of the living God.—MATT. 16:16.

Lord, save us; we perish.—MATT. 8:25.

Most automobiles—in fact, I think I may say all automobiles—have a special and exceedingly important mechanism called the “brake;” and this brake, or system of brakes, is for the purpose of not only checking speed but of bringing the machine speedily to a standstill when occasion may require. The machine I have run for so many years (and so many *thousand* miles) was made with *three* brakes. First, if you pull the starting-lever backward instead of forward it acts as a brake. Besides this brake there is a pedal to be operated by the left foot. This is more powerful, and will, if pushed hard, bring the *engine* almost “up standing,” at once. You might at first thought say, “Why, these two brakes are surely enough;” but, listen and consider. Suppose the chain (or other machinery) that connects the engine to the drive-wheels should suddenly break. Chains wear out, and are often run when they are liable to break and drop clear off the machine. Of what use is your brake on the *engine* when the chain is gone? Suppose you are going up a long steep hill and your chain gives way. Your machine will at once go down backward at a speed requiring the utmost skill of the most expert chauffeur to keep it from a disastrous wreck.

Well, to guard against such contingencies all good machines have what is called an “emergency brake.” This brake has no connection with the engine, but clutches with a grip of steel the powerful driving-wheels of the craft; and the lever that works the device, although out of sight, and as a rule unused, is so close to the driver’s right hand that he can grasp it firmly, if need be, *in the fraction of a second*. I hardly need tell you of the importance of thoroughly testing this *emergency brake* often. If a dog suddenly rushes in front of you, you should be able not only to save the *dog*, but possibly save a smashup of the whole outfit, endangering the limbs and lives of the occupants. Running over a worthless dog recently overturned and made an expensive wreck of a big and valuable machine.

Let us now change the subject a little. Last evening (Wednesday) the leader of our prayer-meeting took the subject of prayer. He asked different members present several questions, and finally gave me the question, “To *whom* should we go in prayer?” In reply I gave the above about the automobile, and finally added we should go to the Lord Jesus Christ, and that it is every Christian’s privilege to find *in him* an “emergency brake” fully adequate to arrest our frail human bark and pilot it safely through *all* life’s emergencies. That little prayer, “Lord, help,” has been my “emergency brake” ever since I started to follow the lowly Nazarene. I have before told you that I have used

it so much that it rings out in my heart like an alarm bell (*all of itself* I might almost say), whenever danger or a crisis appears. When the danger is very great, the prayer is, “Lord Jesus, help.”

I want to give you two instances of how this “emergency brake” works.

One morning years ago, I came over to the factory just before the whistle blew and found the janitor (an elderly man who had been long in my employ) talking vehemently to a group of the hands. He was so much stirred up he did not notice my presence, and kept on. I soon gathered from the smiles from those present that it was my poor self he was rating. Finally he turned so as to discover I was present and had heard his tirade. He stopped a little; but as he was still angry he turned on me and gave me, right before a lot of hands, a regular “blowing-up.” I think his charge was that I was too easy with certain ones that I had particular favorites who broke rules as they pleased, etc. I had opened my mouth to reply and tell him, as pleasantly as I could, to hunt up a better lot of folks to work with; but, sharp and clear, came the “Lord, help!” The “emergency brake” gave orders to say nothing to him at all while he was angry, even though he *had* been stirring up disrespect to his employer. I looked around smilingly on the crowd that had gathered, then walked away with long rapid strides amid the roars of merriment from the group of bystanders. I felt happy over my victory (as the Christian always does), and forgot all about the incident until a long toward noon when the janitor followed me into one of the basements, and, with tears in his eyes, said something as follows:

“Mr. Root, I do not know how I can ever thank you enough for not turning me off on the spot this morning as I deserved. I am out of health, and touchy, I suppose. I don’t think you know how some of them take pains to vex me and hinder me from looking after the interests of the business. You have always been my best friend; and if you will forgive me this time I will try to show you my penitence is not all empty words. I am trying to be a Christian; but I make such poor work of it I sometimes think I had better give it all up.”

He was in our employ several years afterward; and, when near to death, he sent for his old employer; and it was my privilege to cheer him up as best I could ere he took the trip across the dark valley.

Now, friends, suppose I had on that particular morning told him with harsh words to “get off our premises, and never show your face here again!” What would have been the result? He and I would have been enemies the rest of our lives. His Christianity would have received a shock, and *mine too*, for such things *always* “cut both ways.” Don’t you think you had better adopt my “emergency brakes”? It will cost you nothing, for the Savior’s love is as free as the air we breathe and the water we drink. I have outlined in the above two ways of settling a

difficulty. What would be the effect on humanity should one spend his whole life in the way I was prompted to do, rather than the other way?

Before giving the second illustration let me say the dear children, as well as Mrs. Root, have often objected to that portion of these Home papers where I tell of my own temptations and impulses toward selfishness and wrong; and God knows it is no pleasant task to admit I am tempted to be selfish.

I give you these conflicts just as I give you my fights against the wild animals that destroy my chickens, t at you may in like manner come out victorious against the foes of honest industry.

My old father was, while on the farm, greatly interested in raising and selling colts. Well, when he was making a sale he was so careful to tell the purchaser the *faults* as well as the good qualities of the horse in question, that we children used to tell him he overdid the matter, and made out the horse worse than he really was. I hope it was true (bless his memory) that he was more concerned about being *strictly honest* than he was about getting a good round price for his horse flesh.

Now I hope you will excuse me for going into the details pretty fully of a simple little transaction, for there are important *principles* involved in it.

I was away from home, in a town where I was not very well acquainted. I had an important letter to mail and was out of stamps,\* and, still worse, but little money to buy them. It was just before the holidays, and there was so much mail and so many packages that extra help was called into the office. The additional help was only a schoolgirl, evidently; but I presume the postmaster decided she could preside at the stamp-window, even if she had but little experience with money and making change. I laid down a coin, and asked for 25 two cent stamps. After a little time in counting the stamps, she handed them over to me with two coins—a half-dollar and a quarter. Let me digress a little right here. If I should tell you of something I had *dreamed*, no one could tell whether I told the exact truth or not. Only *God* could tell. In the same way, when I tell you of the conflicts that went on in my own mind, only God knows whether or not I am truthful. As near as I can remember, it was in a somewhat absent-minded way I took the coins and the stamps and went over to another part of the office to mail the letter. As I was dropping the letter in the box I was aware my spiritual nature was waking up. The "alarm," or, if you choose, conscience, protested, and I looked at the coins in my hand. I went back to the girl and said:

"Did you not make a mistake? Twenty-five two-cent stamps would be *fifty cents*."

"Oh! I guess I did," she replied, and I gave her back the quarter.

Nothing particularly wrong in the above, is there? I would gladly stop here; but I can

\* I had lost a check I was expecting to get cashed at the bank.

not, and be truthful. I put the half-dollar in my pocket and started to go away; but the "emergency brake" came down harder than ever. My impression, when I laid down the coin for the stamps, was that it was only .0 cts., but when 50 and 25 also *came back* with the stamps, I tried to persuade myself it must have been a *dollar* after all, and decided to let it go at that; but when I was just about to step out at the doorway I recalled that I had searched my pockets just before going to the office, and declared there wasn't a "whole dollar" in my possession. The conflict in my heart probably lasted only a second or two; but one may at times go over a good deal of ground in a second.

Satan, at least once, tried to tempt our Savior. On this occasion I can imagine he tried to argue with *me* in something the same way. He made three different points or reasons why I could honestly keep the coin I was fingering. First, he said, "In these busy times it isn't necessary to count the change you receive. It looks small. Push it in your pocket and go ahead with business. If anybody gives you too much, it is his affair, not yours."

Secondly, he put in, "You are not taking the *girl's* money—of course you wouldn't do that, but what is 50 cts. (that you *need* badly) in Uncle Sam's vast domain with his *tons* of stamps and dollars?" The above is a pretty tough confession for *A. I. Root*, is it not? Perhaps I *have* got it a little strong, just as my old father used to do in selling his colts; but the thought did cross my mind at least faintly. The conductor on a railway was once dismissed because he was "color-blind." He had gradually failed to see any difference in the "color" of the money belonging to the company and that belonging to himself. While I fingered the coin and procrastinated, the color of Uncle Samuel's stamps and money seemed *different* from that belonging to individuals.

My friends, this same "color blindness" that I have been describing will wreck our whole nation and send the whole of humanity to the bottomless pit if we can not get cured of it. Lastly, he suggested that, perhaps, I really *did* have a dollar in my pocket, and the girl was right about it. I suppose this *is* possible, but not at all probable under the circumstances. What ought an honest man and a Christian do when it seems impossible to decide *absolutely* whom the dollar really belongs to—your neighbor (or, perhaps, the great public), or yourself? In a case like this, where you *alone* must decide, what shall you do? Listen to the promptings of the "emergency brake" and say, "God helping me, I will suffer wrong, rather than do wrong, to the end of my days."

I went back once more to the stamp-window.

"I fear, my friend, you have made still another mistake. Do you remember what coin I gave you for the stamps?"

"Why, I supposed it was a dollar—was it not?"

"I am sure it could not have been a dol-

lar, for I did not have a dollar in my pocket." After the coin was in the hands of the rightful owner the emergency brake dropped back out of sight, and I went about my business with a light and happy heart. We are told "a good name is rather to be chosen than great riches," and I want to add that a clear conscience is worth more than all the stamps and money the whole wide world contains. Shortly after, my missing check came in a letter from a Philadelphia firm, saying I had doubtless sent it by mistake.

## POULTRY DEPARTMENT

By A. I. ROOT.

---

### OU! GENERALING THE "VARMINTS," ETC.

I told you in my last that the possum pulled out of our best steel trap twice. Well, after he had in like manner pulled out *five times* I went to the drugstore and got a dime's worth of strychnine, and two big fat possums were found laid out next morning. Later we found another, and three skunks also. No wonder we had trouble with our chickens. A neighbor, Mr. Raub, and, by the way, an old bee-keeper from York State, said our traps were not *set* right. He showed Wesley, so that we are now getting rats and skunks every few days. I have told you the rats of the United States cost our people a *hundred million dollars* every year. How much do prowling wild animals, such as possums, skunks, weasels, etc., cost poultrymen? We have many visitors; and almost every one, no matter what State he comes from, can relate a similar experience in trying to raise chickens. The most of them give it up, and pronounce chickens "too risky." Shall I give it up? Not much! We have an inch-mesh netting put down into the ground, all around our two acres. When we find a place where they have dug under, or *tried* to, we set traps there. My neighbor Rood said my war on these pests was a great blessing to this whole neighborhood.

I do not know that I ever made any thing that gives me more pleasure and satisfaction than the brooder house I have mentioned. I expect to give you a picture of it soon. The netting stapled to the sills goes down into the ground a foot; and just a few nights ago some animal dug down against the netting in several places all around the house. How did he know there were two brooders full of ten-day-old chicks inside? The brooder-house secures three very important things: absolute safety from prowlers; a nice warm place out of the wind when it is cold, and a safe dry place to ramble and play and scratch when it rains or when the grass is too wet to go out.

Not only is there a satisfaction in beating the enemy, but it is some thing like this:

My neighbor Rood says, with a comical smile on his face, when we have a touch of

frost, "If it kills all the stuff north of us there will be no glut in the market, and we Manatee Co. people will get better prices."

Now, don't think from this that Mr. Rood is not a Christian in his planning. He looks at it this way: There is nothing very wrong in looking forward, and planning by every means in your power, so as to have a good crop at just the time many or most people fail. We should be ashamed of giving way or giving up to *preventable* troubles like those I have mentioned.

After I had fenced out and destroyed the skunks, rats, and possums, I had only six chicks left of the 70 that came out of the incubators, and one day a hawk came into the doorway, within a few rods of where I was standing, and got one of the six; but I yelled to such purpose that he dropped him. The chick limped about for a day or two, but now is all right. Mr. Rood came over with his gun, but didn't quite get a shot at the bird. As hawks took a chick or two last winter I have on hand enough three-inch-mesh netting to fence *overhead* a chickenyard 40x75 feet. As no more hawks have appeared, however, we are awaiting further developments. I have taken off another hatch with my two incubators (Cyphers and my own). Quite a few eggs were tested out in five days, and more later; and finally a large number in *both* machines died in the shell after being fully developed. My own incubator gave about 70 per cent of the fertile eggs, while the Cyphers this time gave only about 55. The chicks are now about ten days old, and the two lots are kept separate. Four have died from the Cyphers brood, but none from mine. I fully expected the Cyphers would be ahead, and I can not account for so poor a hatch, especially as I ran it exactly according to directions in a good incubating-cellar.

The Cyphers chicks are in the Clough lampless brooder. My own are in a lampless brooder that I received *by mail* from Boston. It is called the "Lullaby" brooder; and for use in a brooder-house I should place it ahead of all other brooders, not even excepting my own basket brooder. It seems to embrace, more than and other brooder, the principle I have so vehemently enjoined for both chicks and humans; viz., keeping the body warm while the breathing apparatus is right out in the *pure cool* air. The Lullaby is essentially a round box made of corrugated paper and cloth. This box or circle can be let out so as to enlarge it as the chicks grow and need more room. For instance, 25, when first out of the incubator, can squeeze inside of a box about the size and shape of a half-peck measure; but when in such close quarters they must have air; and to let them get it "straight and pure" there are two oval "bay windows," 2½ in. high and 4½ wide. These windows are also used as doors; but at night a row of little heads, even in cool weather, is always close up to both windows. A cushion is arranged with a rattan spring so it will keep its place just over their backs. In such a circular nest

the collective animal heat from 25 little fluffy bodies keeps them abundantly warm, even on frosty nights. As with all other lampless brooders, feeble ones, if there are any seem to need a little heat on cool mornings when all the rest are out running about. It is made by the Park & Pollard Co., 46 Canal St., Boston, Mass. It cost \$1 50, and I think it is worth almost that much to get the idea.

ANOTHER "DISCOVERY."

I told you the only rat-proof feed hopper I knew of was a tall tin can that the rats could not jump into nor out of, and I said such a can would also bother many of the chickens. Well, listen: Get a galvanized iron tub for 50 or 60 cts. Set it in the middle of the poultry house on the ground until all your chickens, old and young, learn to go there for feed. When they all understand it, raise the tub up a little, and finally hang it by three wires from the rafters overhead. If your fowls have access to the house by only a small door near the ground it will be a long time before the sparrows find it. In warm weather, when the doors and windows are open, all such openings should be covered with inch poultry-netting.

POULTRY SECRETS, RECIPES, NEW SYSTEMS, ETC.

I am still investing my money, and sometimes I get a little something valuable. Such books as the Corning Egg-book, however, by the *Farm Journal* people, are worth five times their cost. That is, the price is marked 25 cts., and it is well worth more than a dollar; while the "Miller system," price \$1 25, is hardly worth 25 cts.—see page 718, Nov. 15. I sent the money for the book early in November, but it did not get around until about Jan. 15th. It is a cheap paper book with but a small amount of matter (in very large type) on each page. The plan for warming a brooder at an expense of only "1/2 of a cent a month" is by a manure hotbed, and I will only ask market gardeners what they think of keeping up the heat in a hotbed at the above figure. There isn't a picture, not even of a poultry-house, in this whole \$1.25 book; but there are three or four very good diagrams of feed-hopper, automatic nest, etc., in the fore part of the book. I should say the things he tries to describe are altogether too complicated. I couldn't make such a hen's nest from his description, to save my life. The great secret of feeding a hen a whole year for only "five cents" is, so far as I can understand, by selling the manure for almost as much as the grain costs. Where is there such a market for it? The way to make \$60 a year from each hen is to set every egg and "work for nothing and board yourself." If you carry out the "System" in full, he says you can make \$120 from each hen; and *The Poultry Culture Monthly*, that has been giving the "Miller system" such tremendous write-ups, month after month, in one place says each hen will give her owner \$120 000 a year if the "system" is fully carried out. I suppose the figures are a misprint; but I have seen no correction of it as such. Perhaps it is just

as well to let it go that way, after all, so that others may get discouraged in their ambition to advertise (a "system") something still bigger than any predecessor.

Dear friends, have we not almost "systems" enough already? How about skunks, possums, hawks, etc.?

While speaking of poultry-books I am glad to say some of the incubator catalogs are excellent books for the beginner. The "Artificial Rearing of Poultry," just out by the Prairie State Incubator Co., is worth more than some of the \$5.00 systems. It is written by an educated and I should say *Christian man* and tells the truth about what one may expect from the poultry business. The book is given away, while the "Miller System" costs \$1.25 with its exaggerated and practically impossible statements. It may be urged that the incubator folks have something to sell; but so have the Miller System people; and I doubt if one man in a hundred could make the Miller nest and hotbed brooder, no matter how he tried, from directions in the book.

A SECRET FOR MAKING CHICK FEED.

James M. Brown, Pell City, Ala., advertises a secret for 50 cts. for making a very superior feed for baby chicks as well as older ones. Well, this time the recipe is good, and I heartily indorse it; but, like almost all the others, it is by no means new. It is simply to roast or parch in a slow oven some corn, wheat, oats, kafir corn, sorghum seed, etc., and then grind it coarsely, according to the age of the chicks. I saw the recipe in "Miner's Poultry Book" sixty years ago, and fed my chickens parched corn ground in a coffee-mill, and have used the same more or less ever since. By the way, if you can get some nice clean grain you will find this process will give you about the most delicious and wholesome breakfast food you ever ate, and it is also the *cheapest* food one can live on. Grind it in the little mill I have described on page 30, Jan. 1. The *Practical Farmer* has recently described parching wheat before grinding in the little mills. Serve with a bowl of milk, and see if you do not consider it an acquisition.

---

CAST THY BREAD UPON THE WATERS, FOR THOU SHALT FIND IT AFTER MANY DAYS.—ECC. 11:1.

The following came as a postscript to a kind letter from one of our readers now 67 years old. May God be praised for such testimony. Are there any more of the "veterans" who received a smoker and "kept the pledge?"

It is now about 30 years since I received the gift of a smoker from you, conditioned on my discontinuing the use of tobacco. I have never used tobacco since. I have often wondered how I could have been so selfish all those years in gratifying my own pleasure in a manner so offensive to others from a simple want of thought, for all through my long life I have always been considerate of the feelings of others; but only in the use of tobacco did I fail to realize the enormity of my selfishness, and I have always since connected the name of A. I. Root with that kindly action in days long passed by.

## EDITORIAL

By E. R. ROOT.

### THE IMPORTANCE OF THE WINTER NEST.

ONE of our subscribers, Mr. R. C. Hugentobler, of Miami, Ohio, has this to say of the importance of a winter nest:

As I have supplied many colonies with sealed stores, and taken many observations, I find that what you say in regard to the winter nest is true. I have found that colonies supplied with sealed stores are invariably not clustered on them, but hang to the dry empty combs, and starve, sometimes, when in touch with the sealed stores. These observations prove conclusively to my mind the great importance of a winter nest in outdoor wintering.

### PRICES ON HONEY NOT KEEPING PACE WITH OTHER FOOD PRODUCTS.

In looking over the back volumes of GLEANINGS for 1877, we noticed how Adam Grimm reported that he was getting 25 and 30 cents a pound for his extracted honey; that he thought 25 cents was low enough. This makes rather interesting reading when we consider the present price of extracted honey, and that all other articles of food have advanced. The reader, in this issue, will be interested to follow the discussion of this question by Mr. O. L. Hershiser, on page 140.

### DANGER FROM DEAD BEE-CLOSED ENTRANCES.

AT this time of the year, especially after a very severe winter such as we are now having, it will be very important to see that dead bees accumulating in the entrances of outdoor-wintered colonies be raked out. An entrance closed with dead bees, snow, and ice usually means death to a colony. There is great danger that hundreds of colonies in otherwise good condition may be lost through a lack of attention at this season of the year. If the outdoor-wintered bees have absorbing cushions the results will not be as fatal; and that, by the way, is one thing in favor of that kind of wintering.

### WINTER LOSSES.

It begins to look now as if there would be heavy losses of bees in some sections. The winter thus far has been one of the old-fashioned kind, with almost continuous cold without any flying days. This, for our locality, is something unusual. While our bees are wintering nicely because we fed a large amount of sugar syrup, we have been a little fearful that the large amount of

honey-dew, where no syrup was fed, together with the extremely cold weather, was going to have a bad effect upon other bees.

### AMERICAN HONEY REFUSED ADMISSION IN SOUTH AFRICA.

THE following letter, received from the Bureau of Entomology, will explain itself:

UNITED STATES DEPARTMENT OF AGRICULTURE,  
BUREAU OF ENTOMOLOGY,

Washington, D. C., Jan. 3.

Mr. E. R. Root:—It has come to the notice of this Bureau that certain shipments of honey from California, which were sent to England and there bottled and shipped to the Cape of Good Hope, have been refused admission to that colony under Proclamation No. 394 of 1908 of the Governor of the colony. This proclamation states that, since "the disease known as 'foul brood' exists or is supposed to exist among bees in Australia, New Zealand, the Continent of North America and the Continent of Europe, including the United Kingdom and Ireland," the importation of honey from these countries is prohibited "except under written permit previously obtained from the Secretary for Agriculture, under such restrictions and safeguards as may seem to him expedient or necessary."

This proclamation, therefore, prohibits the exporting of all American honeys to the Cape of Good Hope, whether or not either of the diseases of the brood exists in the apiary or apiaries from which the honey is obtained. Steps are now being taken to obtain permission from the Secretary for Agriculture to allow shipments of honey from healthy apiaries to be admitted to this colony when proper proof is presented that no disease exists. The form of permit or certificate must be determined by the officers of the colony. This proclamation puts a stop to the sale of considerable quantities of American honey which has formerly been sent to the Cape of Good Hope until some arrangement can be made with the Secretary of Agriculture. L. O. HOWARD, Chief of Bureau.

### SOME OLD PATENTS BEARING ON SOME SCHEME FOR PREVENTING FOUNDATION STRETCHING.

IN our last issue, page 99, reference was made to the fact that an inventor had lately patented a scheme for using paper in the midrib of foundation to prevent its sagging while being drawn out by bees. Having occasion to go over our file of patents relating to apicultural inventions, we ran across a patent issued to J. Y. Detwiler, May 13 1879, covering the use of perforated tinfoil in the midrib to prevent stretching. On Aug. 13, 1878, M. Metcalf took out a patent for the use of cloth dipped in melted wax and run through foundation-rolls or flat dies.

It was about this same time that A. I. Root used quite extensively paper in the midrib of his foundation sheets; and while he did not patent the same he wrote it up in GLEANINGS. He found that the bees, during a dull season, would discover the paper in the combs, when they would immediately begin to tear it out. They seemed to think it

was the silken galleries of the mothworm, and they treated it accordingly. We had hives of Italians that just fairly riddled their combs after they had been nicely drawn out.

All these different schemes for fixing foundation so it will not stretch are quite alluring; and to one who has never worked them out, any one of them appears to be perfectly feasible; but "there is many a slip 'twixt the cup and the lip" in apiculture.

In this connection perhaps it would be interesting to note that Capt. J. E. Hetherington, the one-time largest bee-keeper in the world, patented the plan of using wires imbedded into foundation. Two patents were issued to him—one dated August 28, 1878, and July 14, 1879. The first patent covered the use of wires in any foundation, whether having natural base or flat base. The second was limited to the use of wires in flat-bottom foundation.

#### SOMETHING MORE ABOUT RYE MEAL AND BROOD-REARING.

AFTER the experiment of feeding rye meal under glass I made examination of our colonies outdoors and found quite a number without a particle of pollen, and, as a matter of course, *no brood*, although the queen laid eggs every day. As the weather was such the bees could not fly, I began experimenting with rye flour mixed with honey so as to form a sort of dough, and was delighted to find this food started brood at once, just as the rye did in the greenhouse. Whenever or wherever colonies are found destitute of pollen I feel sure it will pay to supply it in this way until they can get it from natural sources. As it sometimes gets so hard in the cells that even the bees seem unable to remove it, we should be careful to give them only about enough for present use. I think this matter is given at length in our early volumes; but I have no access to them here in my Florida home.—A. I. R.

#### CARBOLIC ACID WILL NOT KEEP BEES AWAY FROM POISONOUS SPRAYING-MIXTURES.

REFERRING again to the statement made p. 611, Oct. 1, by B. W. Harrington, in regard to carbohc acid being used in spraying-mixtures to repel the bees and prevent them from being poisoned, we have found that quite a little interest has been shown by our readers. Mr. J. L. Byer, page 778, Dec. 15, reported that it was his belief that this was all a mistake. Prof. Surface's opinion was used in our last issue, page 127. We are just in receipt of a letter from Prof. C. P. Gillette, State Entomologist for Colorado, which explains itself.

I have not heard of carbohc acid being used in spray materials to prevent bees from being poisoned. Unless some one has tested this plan and found it to work satisfactorily, I should be very much inclined to doubt its having any repulsive effect upon the bees. Entomologists have used various odorous substances for the purpose of preventing insects from attacking the plants, but almost wholly without results. It is the instinct of the honey-bee to visit the blossoms that contain pollen and honey, and I do not believe it would be practical to use enough carbohc acid in spray material to drive them away. It is a grave mistake for

any fruit-grower to use an arsenical spray for the purpose of killing codling moth before the blossoms are practically all off his trees. I have talked this to the apple growers in Colorado for the past 19 years, and I do not think we have any trouble at the present time from orchardists spraying their trees while they are still in blossom. We did have some trouble, however, a few years ago along this line.

Fort Collins, Col.

C. P. GILLETTE.

#### YOUNG PEOPLE WHO HAVE PAID OR ARE PAYING THEIR WAY THROUGH SCHOOL FROM MONEY EARNED FROM KEEPING BEES.

MARY ROGERS MILLER, 340 Rahway Ave., Elizabeth, N. J., is writing a book for Doubleday, Page & Co., of New York, on outdoor work for young people. She has given considerable space to the subject of bee-keeping. One part of the book is to be devoted to stories of real boys and girls who have made all or a part of their college expenses, their pin money or pocket money by engaging in some form of outdoor occupation. Mrs. Miller is particularly anxious to get in touch with young bee-keepers who with the money they have earned have gone through school or college. We hope that any subscribers who know of any such persons, or who themselves, in fact, come under the class mentioned, will write to Mrs. Miller direct.

In the meantime we have been informed that a daughter of Mr. J. F. McIntyre, one of the extensive bee-keepers of California, paid her way entirely through college with the money that she made off from her own bees. There are doubtless many others among our fraternity who have done the same. All interested should write to Mrs. Miller at once.

#### KEEPING ALFALFA COMB HONEY FROM GRANULATING.

A YEAR or so ago, our readers will remember that we conducted some experiments in an incubator to determine whether we could bring candied comb honey back to a liquid condition without melting the comb. We partially succeeded; that is, we succeeded to the extent that the candied particles in the honey were liquefied, but the temperature necessary to do this caused the comb to sag a little. That temperature was 106. Last winter we tried the experiment on a larger scale, but did not allow the mercury in the thermometer to go higher than 103. While we could not at this temperature undo the work of granulation, we arrested its progress almost instantly. This room was about 6×6×7 feet high. It had a steam radiator in it and an automatic regulator to control the temperature.

Again, this winter we noticed that quite a little of our last two carloads of alfalfa comb honey were beginning to granulate slightly. Something had to be done at once. We selected a room of sufficient size to hold the honey, and put in additional steam radiation till the temperature could be brought up to about 90. Here the honey was stored and it has been there for the last month. It was gratifying to observe that the progress of granulation was arrested at once.

From all the experiments we have conducted, we have concluded that it is not practical to liquefy the granulation in comb honey. We can arrest the progress, when it just starts, at a temperature of 90 degrees. If it has progressed a little further a higher temperature would be required to stop it. Those who have honey stored in large quantities, especially if it be alfalfa, should remember the very great importance of keeping it in hot rooms. We have visited many commission houses in the country, and too often the rooms where the honey is stored is down to a temperature of about 60. Ordinary farm produce can be kept better in a room like this, no doubt, but honey should be put into the warmest, hottest, driest place on the premises. The average commission man and honey-buyer can well afford to put in extra radiation in some special room where his honey is stored—enough radiation to hold the temperature approximately between 85 and 90 degrees *night and day*. It is important that this temperature be kept *uniform*. It will not do to have the thermometer show 90 degrees at one time and 60 at another. This is just the very thing that will hasten granulation.

In some of our early experiments we determined that alfalfa honey may be stored in a room that is kept at zero temperature for almost two weeks steady and yet no granules will show; but the minute it begins to warm up, changing from warm to cold, then the honey will begin to cloud and finally turn into a solid condition. Apparently, then, a very cold temperature or a very warm temperature is less favorable to granulation than any point between; but we would by no means advise any one to put his honey in a room subject to a zero temperature. Comb honey, of course, would be frozen, combs would crack and the goods would be ruined.

#### FORMATION OF THE OHIO BEE-KEEPERS' ASSOCIATION AND THE INTRODUCTION OF A STATE FOUL-BROOD BILL.

THAT the bee-keepers of Ohio have not been idle during the past few weeks will be shown by a report received from the secretary, Mr. Henry Reddert. We take pleasure in presenting it here at this time.

Feb. 3 and 4, 1910, the Ohio bee-keepers met at the Neil House, Columbus, Ohio, and organized the above-named association. The following officers, to serve for one year, or until their successors are chosen, were elected:

President, J. F. Moore, Tiffin; Vice-president, Henry Shaffer, Westwood; Secretary, Henry Reddert, Cincinnati; Treasurer, C. H. Weber, Cincinnati; Executive Board, E. R. Root, Medina; Henry Hastings, Kenton; Dr. P. E. Cromer, Springfield; D. H. Morris, Springfield; Pearl McIntire, Springfield; Edward W. Peirce, Zanesville.

A bill was drafted having the general features of the one recommended by the Bureau of Entomology, at Washington, D. C., authorizing the State Board of Agriculture to establish a "Division of Apiary Inspection" in the Ohio Department of Agriculture. This bill provides that the Board shall appoint a competent entomologist as chief inspector of said division, with power to appoint the necessary assistants, who shall, under the direction of the board, have charge of apiary inspection. Mr. A. P. Sandles, Secretary of Agriculture, and several Representatives of the different counties of the State were seen, and the provisions of the bill explained.

All the members of the association present were very enthusiastic in the work before them, and expressed the hope that this bill will clear the bee-yards of foul brood and all other diseases common to the honey-bee. Mr. E. R. Root worked like a beaver. He acted as a spokesman, and introduced the association committee to the Secretary of Agriculture in the capitol building. In clear and concise language he explained to that gentleman the wishes and wants of the Ohio bee-keepers. He made so favorable an impression that the Secretary offered a column in the *State Agricultural Journal* to further the art of bee-keeping. In a few days the bill will be ready for introduction to the General Assembly. In the mean time every bee-keeper in the State should call the attention of his Representative to the bill when it comes up for discussion and passage, and ask him to support and vote for it.

The various bee-keepers attending this convention came to this meeting for the sole purpose of clearing the bee-yards of disease, and such efforts should in every way be crowned with success. The bill will appear in GLEANINGS in due time. Next year, probably in January, when the horticultural societies meet in Columbus, the Ohio bee-keepers will hold their next annual convention. In the mean time the officers of the association will communicate to each other every detail enhancing the growth of the State organization, getting all the bee-keepers they can to join.

Communications should be sent to Henry Reddert, Secretary, 2300 Schoedinger Ave., Lick Run, Cincinnati, Ohio.

Perhaps we should explain that the bill which the bee-keepers of Ohio are about to have introduced in the legislature does not call for any special appropriation. It was found that the present legislature would be very much disinclined to pass any bill carrying an appropriation of \$500 or \$1000. Prof. N. E. Shaw, State Entomologist, and Mr. Sandles, Secretary of the Department of Agriculture, very kindly offered to take care of the work of inspection out of the general appropriation granted to their Department, providing that, for the first year, we bee-keepers do not make too heavy a demand upon them. For the present, at least, if the bill is made into law, granting police authority to the State Entomologist, he could appoint one or more of his nursery inspectors to act also in the capacity of inspectors of apiaries. This could be done for the first year, or until more funds are available, to save expense. While the objection might be raised that nursery inspectors would not be competent to pass upon the diseases of bees, it will not take them long to become informed regarding the nature of the two principal bee diseases that are so destructive in the United States; and, besides, the members of the Ohio State Bee-keepers' Association have offered to render them every assistance, not only in informing them *where* disease exists in the State, but *how* to recognize it. For the first few trips it will doubtless be necessary for the inspectors to call in one or more competent bee-keepers in the locality to advise.

While the amount available for inspection work will probably not be large this year, yet if we can *once get this bill through*, granting police authority to the State Inspector (the State Entomologist), the Secretary of Agriculture a little later on can make provision for the necessary funds to carry on this important work properly. Both Prof. Shaw and Secretary Sandles seem very willing to help us.

## STRAY STRAWS

BY DR. C. C. MILLER, MARENGO, ILL.

HOW SOON after a colony becomes hopelessly queenless may laying workers set up business? [This is something that varies according to the strain of bees and conditions. With Holy Land bees, laying workers will develop much more quickly than with Italians. Cyprians come next.—ED.]

FOOD-INSPECTOR DODGE, testifying before Congressional committee, gave prices of necessities of life in 1897 and now. Of 16 leading items, the advance has been from 33 to 145 per cent. The sum of their prices is now 76 per cent higher than it was. Can any one figure out that honey has advanced 76 per cent?

F. DUNDAS TODD, you wanted to feed a pollen substitute Jan. 1, and it sounds a little as if you thought bees died for want of pollen, page 122. I don't believe a bee died from that cause, and in winter not a grain of pollen is needed, nor until time for brood-rearing to begin, for no brood can be reared without pollen. Notice, the editor says *brood* died for want of pollen but not bees.

FOR ROBBER-TRAP escapes, p. 116, why not two cleats nailed on hive-wall, V-shaped, with wire cloth nailed on flat? Your presentation has converted me into a belief in robber-traps. [Possibly a bee-escape could be made in the manner you describe, especially if made double; but the wooden cleats would be more inclined, in our judgment, to direct the entrapped workers back to the point of apex through which they could get back by the way they came.—ED.]

DOBBRATZ says, *Wegweiser*, 9, that fertilization of a virgin may occur when she is even 6 weeks old, and only in the rarest cases will she become a drone-layer before that old. If she once starts drone-laying she will never be fertilized. If within this time drone brood is found, it is certain that laying workers are present, and will continue work until the queen begins laying. He and others have had laying workers thus begin with a queen-cell or a virgin present.

"QUEENS reared late . . . may not be the equal of those reared early in the season," p. 108. I'm afraid some beginner will understand that "early" to mean before there is any honey-flow. In this locality the normal time for queen-rearing begins with the white clover flow unless sometimes in a heavy dandelion or fruit flow. A queen reared before this time is apt to be worthless, and I don't believe any amount of feeding will make her good. On the other hand I *think* feeding may make a good queen after the honey-flow is over. At any rate I would much rather have a too late queen than a too early one. [Thanks for correction. We meant by "early queens" those reared just about the approach of a honey-flow. We do not agree with you, however, that an early-

reared queen raised, say, in May, can not be as good as one reared in August. If one knows thoroughly the art of queen-rearing he can, by a process of making a colony combless and broodless, and feeding, produce results that are as good as those secured during the swarming season; and in this connection it is proper to state that not all swarm cells by any means are first class. Many of them are much inferior to those reared under artificial conditions. Nature does not always do better than science; but as a rule science can not often hope to excel her.—ED.]

SUPPOSE each of 100 colonies to have its queen removed and at once replaced by a virgin just hatched; how many of the 100 will swarm with the young queen? In other words, how many chances in a hundred are there that a colony thus treated will swarm? [Instead of asking the question we wish you had answered it yourself to the best of your knowledge. We infer from the way you *put* the question that you think the number of colonies that would swarm with a young queen would be small. Is our inference correct? In the mean time, perhaps you would like to know *our* views. We have nothing very definite to offer except that colonies with young queens are much less inclined to swarm than those with old ones. What the proportions would be we could not say. One of the most extensive bee-keepers in Ohio, Mr. Henry Hastings, of Kenton, told us that it was his practice at the beginning of the honey-flow to kill the old queen, and in eight or nine days destroy all the cells but one and allow the virgin issuing therefrom to become the mother of a colony. By so doing—and he is an extensive producer of comb honey—he controls swarming almost entirely.—ED.]

HOW MANY fielders are in a colony of 50,000 bees? If a queen has been laying the same number of eggs each day for many days, if the average life of a worker is 6 weeks, and if each bee spends 16 days as a nurse before becoming a fielder, then  $\frac{1}{32}$ , or 19,048 bees, will be nurses, and  $\frac{2}{32}$ , or 30,952 bees, will be fielders. Earlier, when the daily output of eggs is on the increase, the proportion of fielders will be smaller; later, when the output is on the decline, the proportion of fielders will be greater. I am not ready to swear to those figures, and if any one has a better answer I'll be glad to get it. Even if my figuring is correct for a strong colony, it will not be correct for a weak one; for enough bees must stay home to keep the babies warm, even if it makes them stay till they are much over 16 days old. [Your figures are doubtless fairly correct for average conditions; but we know that, under abnormal conditions, nurse-bees will assume the function of fielders, and old bees the function of nurse-bees. Assuming that your figures are fairly correct for average conditions, they go to show the importance of strong colonies in order that the proportion of fielders may be sufficiently large to get the honey that is in the field.—ED.]

## NOTES FROM CANADA

BY R. F. HOLTERMANN.

### PROVINCIAL GOVERNMENT ESTIMATES.

The Supplementary Estimates for Ontario contain the following items of interest to bee-keepers: An increase of \$500 to provide for inspection of apiaries and traveling and other expenses in connection with apicultural work; \$1200 to provide for lecturer on apiculture at the Ontario Agricultural College, and \$750 to provide for equipment and maintenance of the Apicultural Department. I understand, however, that there may be some further provision.

Later.—The provincial apiarist's salary is now \$1500.

### THE NORFOLK BEE-KEEPERS' ASSOCIATION.

This association was organized Jan. 13, 1882. It has had 97 meetings, and has been one of the most active local associations in Ontario. In progressive movements it has been well in the lead, particularly in late years. More than one plan which it has instigated have been brought to maturity. Its present officers are, Edwin Trinder, Pres., Simcoe, Ont.; John Murphy, Silver Hill, Ont., Vice-pres.; and Lee Beaupre, Forestville, Ont., Secretary and Treasurer. All of these are men who, when they undertake a work, do not readily turn from it. Messrs. Trinder and Murphy are well known in other activities. The Secretary, Mr. Beaupre, has been a hard worker in the interests of the association, and deserves the thanks of the bee-keepers in the section of the country which covers its activities.

### BEE-KEEPING IN RUSSIA.

On page 23, *British Bee Journal*, there appears a very striking editorial on the above subject. It contains in part as follows: "It is said that in the government of Ekaterinoslav, in South Russia, there are nearly four hives to every inhabitant." If I mistake not, the district referred to is somewhat densely populated, and it would be highly interesting in this connection to have some information on this subject. In any case, in this country many would be inclined to think four colonies to every inhabitant would be overstocking with a vengeance. Again, "In Little Russia, before its union with Russia proper, there existed a tithing in bees, which consisted in carrying to the seignior a tenth part of all the honey produced in the hives. At the beginning of the eighteenth century a single forest domain of the government of Kiev paid the seignior annually as much as 200 barrels of honey, each barrel weighing 361 lbs." This means 72,200 lbs.

### QUEEN-EXCLUDERS.

On page 26, Jan. 1, a writer discusses the question of using queen-excluders, doing it in a fashion all too common on this side of the ocean. D. M. Macdonald, Banff, who is

beginning to be known as an apicultural writer, has previously, in defense of the use of queen-excluders, quoted such men as Dr. Miller and Mr. Doolittle. - Then he states, as regards "advanced" American bee-keepers, "let us look at just a few of their up-do-date methods." Then Dr. Miller is shown up as a man who does not paint hives, and, "incredible as it may appear, actually places a diseased comb for several days in the hives containing the turned-out (diseased) lots."

Then Doolittle has it thrown up to him that "He puts a couple of boards on the ground in the apiary, and piles thereon his reserve supers of honey, with no other protection than a hive-cover on top; and there they remain from October to the middle of June."

These practices would certainly, in my estimation, be very bad; but if it is all a correct statement, there has nothing then been said in favor of the abandonment of queen-excluders. As long as I can secure queen-excluders I do not care to do without them; in fact, I would almost as soon do without comb foundation in the brood-chamber.

### AN ACT RESPECTING THE RIGHT OF PROPERTY IN SWARMS OF BEES.

The Hon. J. S. Duff, Minister of Agriculture for Ontario, has introduced an act in connection with the above which will, no doubt, become a law, as it is a government measure.

"Bees living in a state of freedom shall be the property of the person discovering them, whether he is or is not the proprietor of the land on which they have established themselves. Bees reared and kept in hives shall be private property. Where a swarm of bees leaves a hive, the owner may reclaim them so long as he can prove his right of property therein, and shall be entitled to take possession of them at any place on which the swarm settles, even if such place be on the land of another person; but the owner shall notify the proprietor of such land beforehand, and compensate him for all damages.

"If a swarm settles in a hive which is already occupied, the owner of such swarm shall lose all right of property therein.

"An unpursued swarm which lodges on any property, without settling thereon, may be secured by the first comer unless the proprietor of the land objects.

"If the owner of a swarm declines to follow the swarm, and another person undertakes the pursuit, such other person shall be substituted in the rights of the owner, and every swarm which is not followed shall become the property of the proprietor of the land on which it settles, without regard to the place from which it has come."

### "FLOURING" BEES SHAKEN IN GRASS.

Instead of shaking bees on to the bottom of the hive I shake out in front of the hive several feet away. When ready to drop the queen among them, sprinkle flour on the bees. They will get into the hive in one-fourth the time it would take to smoke them in. It seems to demoralize them completely.

Colo, Iowa.

D. E. LHONMEDIEU.

## BEE-KEEPING AMONG THE ROCKIES.

BY WESLEY FOSTER, BOULDER, COL.

### ANGLE OF CELLS BUILT FROM FOUNDATION.

Dr. Miller, the reason for the *side* of the cell being horizontal in comb built from surplus foundation and the *angle* of the cell pointing to the top in the brood foundation, p. 23, Jan. 1, is that the surplus foundation is cut across the width of the sheet while the brood foundation is placed in the frame lengthwise; so if you would attach what was the side of your foundation sheet to the top of the section the angles of the cells would point the same as they do in brood foundation and in most natural-built comb.

### GLASS-FRONT CASES.

Mr. Crane, page 37, Jan. 15, thinks the unglazed paper case will sell in competition with the glass-wood case. If the paper case would ship more safely than the wood case it might be true. I do not doubt that the paper case would outsell the single-tier wood case; but the double-tier case will ship much more safely than the single tier.

When the buyers will pay 10 to 15 cts. more for honey in double-tier glass front cases than for that in single-tier wood-slide cases, it is reasonable to suppose the bee-keepers will supply the better-priced article.

### DEPTH OF SHIPPING CASES.

On page 455, Aug. 1, I had reference to the double tier case needing an eighth-inch space over the sections. More space than this would endanger the sections should the case be tipped on end or upside down. It would not do at all to make the single-tier case with a 1½-inch space over the sections as Mr. Crane suggests on page 758, Dec. 15. What would happen if such a case should go on its side or end, or clear over? and yet I do know that the covers sag as Mr. Crane says, when stepped upon, and that is the chief fault with the single-tier case. The double-tier case cover will not sag more than a sixteenth of an inch, because the heel and sole of the shoe reach nearly across the cover.

### THE SOLAR EXTRACTOR.

No method of melting and molding wax can excel the solar wax-extractor when properly handled. Refuse must be kept out of the molding pans, and this can be done by having the screen form an obstruction to the melted wax so the bits of foreign matter will settle or lodge. The screen makes all the better sieve if it is clogged with slumgum and cocoons.

The extractor should be opened in the morning early before flies are about. The practice of leaving a cake of wax in the extractor from day to day is a poor procedure. The cakes form in layers, and refuse is almost sure to be between the layers. Take

out each day's run the next morning before or about sunrise. It is better to have thin cakes than thick layer cakes with dirt sandwiched between.

### CORRUGATED-PAPER SHIPPING-CASE.

Too much can not be expected of the strawboard case. Several cases of these came to Denver from a distance of several hundred miles. The shipper apparently thought they would stand any amount of rough handling by the express company, for no marks were put on to tell what the contents were. Three-fourths of the honey was broken out; and what was not broken was cracked badly. A wood case with glass front would go through much better, for the fragile character of the contents can be seen. The strawboard case will stand rougher treatment than the wood case, but it must not be dropped far in cold weather.

### HONEY GRANULATING.

When honey in the comb begins to granulate, the granules form around the sides of the cell, leaving the center liquid. Perhaps this is not true in every case, for in some samples in which the honey was getting mushy, I have found all the honey in the cell of like consistency. Most of the honey here in the West, however, begins to granulate on the sides of the cells, and then spreads throughout the cell. Often quite a little time passes before the honey is candied solid. Some combs will remain a third candied for five or six weeks. Where the granules have formed only on the sides of the cells it is very difficult to tell whether the comb honey is candied or not without breaking the cappings. These combs, if held up so light will shine through, often look clear and bright, though not quite so clear, I imagine, as the article that is wholly liquid.

### B'ITS IN SUPERS.

The use of a bait in the super is to start work above before the brood-nest is so crowded that swarming soon results. Baits placed in the corners will not be worked in much more quickly than sections of full starters in the center of the super. In my opinion a colony that will work in any part of a super is strong enough in bees to do good work above if the flow is daily getting better. Bees will not fill four or five baits in the center of a super till there is a rather plentiful amount of stores below. In this country I know the control of swarming hangs around the few days after the lower hive is well filled before we get the bees fully convinced that supers are the next on the program and not swarming. This whole question of placing baits depends on what the aim is. With our bees baits are used to get super work started, not to insure uniform super work; that can be had by spreading the nearly finished combs to the outside when the bees are fully possessed with the super idea.

## CONVERSATIONS · WITH DOOLITTLE

AT BORODINO, NEW YORK.

### IS AN EXTRACTOR NEEDED FOR 23 COLONIES?

"I have been in the business only two years, and have twenty-three colonies at the present time. Mr. Jones told me yesterday that I should have an extractor, as many hives would often have too much honey in them in the spring; consequently the queens would be cramped for room to deposit their eggs, and that in such a case I could use an extractor to advantage to give the desired room, and at the same time put a stop to any inclination to swarm. In all of his experience he said he had never had a swarm at any time when the queen had been supplied with plenty of empty comb in the brood nest. He further said that, in this way, I could be sure of having very strong colonies when the honey harvest commenced in earnest; and in case of a short flow I could secure quite a crop of extracted honey, while if I depended on comb honey I would get lots of swarms, with very little or no salable honey in sections."

"Well, Mr. Smith, there is some truth in what he said, and some things which are not what a practical apiarist would advise. That you could secure some extracted honey in a season with only a few days of honey flow is true; and that you would not have any swarms where the queen was supplied with all of the empty combs she could use for laying purposes, is nearly correct, though there are a few who claim that they have more or less swarming, even under such circumstances. But when Jones recommends extracting the old honey in the combs which the bees stored the year before, most practical bee-keepers would tell you he was making a mistake. In most if not all localities such honey is needed for brood-rearing before nectar of any amount comes in from the early or spring blooming flowers, and to extract it for the fun of feeding it back again would not be considered a paying job, as most of us believe that brood-rearing will go on just as prosperously, if not more so, when there is plenty of honey in the hive, without taking out some of it and feeding it back. Labor is one of the great problems in apiculture; and extracting this old thick honey, and then thinning it and feeding it warm, a little at a time each day, makes the labor problem very much greater than it is otherwise."

"Then you would not advise me to buy an extractor to use in that way?"

"No, I would not. But no person having as many as 20 colonies can afford to go without an extractor. Have you not had some colonies that were adverse to going into sections? or others that had the swarming fever, so that a whole season passed without a proper surplus? When you find colonies which are reluctant about working in the sections, just take a hive filled with combs

to one of them; open the hive and take out one or two combs of brood, and replace with an empty comb or two, as the case may warrant; then place a queen excluder over the hive, and on this excluder put the hive you brought along, and, when spacing the combs in it put in those you took from the old hive, after shaking the bees off, so you are sure you do not get the queen. You will now see that work takes the place of loafing. When the bees have those combs filled with honey, which they will have in a week or so, the extractor comes in play by throwing out that honey; then, on the return of those emptied combs, the bees will work with renewed energy to fill them again. Again, some colonies seem bound to store the larger part of their honey in the brood-combs, thus crowding the queen and causing swarming, or leaving too few bees for winter. Especially is this the case where the dark or leather-colored Italians are kept.

"An extractor and the treatment I have been telling you about are almost the only salvation, if I may be allowed that expression, the apiarist has with such bees. They are excellent for extracted honey; but on account of their propensity to crowd the brood-chamber with honey, and cap their honey so it has a watery or greasy appearance, they are better for extracted than comb honey."

"I am glad you touched on this subject, for I had several colonies last year of these dark Italian bees that filled their hives full of honey, but put very little in the sections; and what they did put there was so miserably capped that I had to take second price for it by the side of what was made by my blacks."

"If you have an extractor, with such colonies you can become master of the situation, and secure a good return in extracted honey, which, when the selling price of this is added to that from your section honey, will bring the total amount to where you will have a good showing from each colony."

"But how can I dispose of so much?"

"You would have no trouble at all with what you get from your 23 colonies. As fall draws near, at which time every family wishes honey, even though they may not wish for it strong enough to come to you for it, take a sample of this extracted honey and leave from two to four ounces at each house, telling the people, and especially the children, to sample it, quoting the price you have decided to sell at, and say you will be around with the honey on such a day. When the day comes, take it to them and see if you do not dispose of three times as much as you had hoped to. After this one baiting of all the families within a radius of five miles of your apiary, all you will have to do in future years is to let it be known that you have such extracted honey for sale, and you will find yourself short each year, if you produce the good thoroughly ripened sort, which you should always do."

"How much would you think a market built up in that way would take?"

"From 1000 to 5000 pounds, depending on the population or the number of villages."

# GENERAL CORRESPONDENCE

## SOME OBSERVATIONS ON MARKETING HONEY.

**Unequal Distribution; the Uninformed Bee-keeper and the Devious Methods of Some Honey-buyers the Source of Low Prices.**

BY OREL L. HERSHISER.

Continued from last issue.

From the foregoing it is apparent that, under normal conditions, honey sold to the wholesale dealer at the jobbing price, and by him to the retail grocery, appears to require an advance of from 40 to 100 per cent before it reaches the consumer. In other words, honey which is sold by the producer at from 14 to 16 cts. costs the consumer from 20 to 30. As profits and opportunities for purchasing and selling are variable it will be understood that the above figures are approximate; but they are sufficiently accurate to serve the purpose of this discussion. To apply the above figures to a specific example easy to understand: If a bee-keeper has a crop of honey worth \$1000, if sold at the jobbing price, the consuming public pays from \$1400 to \$2000 for the same, which is the amount the bee-keeper should receive for such honey crop if he sells to the consumer direct, except a reasonable discount equivalent to the difference in the labor and expense resulting from putting the honey up in containers of considerable size for the family trade instead of the small containers handled by the grocery trade. Need any thing further be said in favor of the producer retailing his own honey? Let every bee-keeper who can do so retail his own crop, as far as possible, classifying his customers as above pointed out; and if he is a good salesman he will be abundantly compensated for the extra work; and, coming in direct contact with the consuming public, he is able to educate it to the use of honey as only the practical bee-keeper can.

The bee-keeper should cultivate and develop his ability as a salesman. He should study what to say and what to leave unsaid. He should acquire the art of versatility. A certain line of argument or discussion will win one customer while entirely different tactics are required with another. Let whatever you say about your goods be the truth. You produced the honey, and know all about it. You were present from the time the bees began work in the spring until the crop was secured. You know how the bees were built up for the harvest; when the supers were put on; when you took them from the hives; with what care you kept the different kinds of honey separate, and how you allowed it to remain in the supers with the bees until thoroughly ripe.

Be persistent but not obtrusive. A jovial

and gentlemanly demeanor is a winner. "Vinegar never catches flies." A naturally sour or dyspeptic person may become interested in honey in spite of herself if the salesman, with seeming carelessness or indifference, will manage to drop a remark that will awaken interest before madam closes the door; such, for example, as "My bees are the Italian race, which are reputed to be the best honey-gatherers;" or, "I make a specialty of bee keeping and honey-production, and my honey is as fine as bees can make it," or some other interest-inspiring comment. Having gotten upon conversational terms with your prospective customer, an ordinary talker can easily keep up the interest on the attractive subject of bees, and a sale is likely to be made and a steady customer secured. Most people are anxious to learn, from one who actually knows, all about honey and the mysteries of the honey-bees.

Spend no time or talent in "knocking" other bee-keepers or retailers. It is true that many of them seem to think a good way to get customers is to hunt up those some other person has educated to the use of honey, and, in order to make a sale, quote a reduced price. It is true you are obliged to do just what they should have done—go and hunt up and educate to the use of honey a customer or customers to take the place of those you have lost to the cut-price retailer. But do not say hard things about him. Pass it up; and when the selling season is over, and your pockets are bulging out with the currency of the realm because of the fair prices you have received, while his have a lean emaciated appearance because of having done an unprofitable business, he will be ashamed of himself; but if he should ask you for a loan it will be yours to reply, "My friend, hereafter *stick to established prices* and your pockets will bulge as do mine;" or, "Go to the ant, thou sluggard."

The bee-keeper who retails his honey should study well the matter of containers to ascertain, as nearly as possible, the size with which he can sell at the greatest profit. Having fixed the price for the family trade, the larger the container the more honey will he sell, for this is not the "hand-to-mouth" sort of customer.

For the retail grocery trade the smaller containers are best. In selling to families, offer the larger-sized package first, and sell the smaller sizes only when the larger sizes will not go. Sell tin pails gross weight, and you thus get paid an equivalent for the pail. If necessary, explain why it is sold gross weight. Glass fruit-jars should be charged for at their value besides the value of the honey. Jelly-glasses are sold by the dozen.

There are great possibilities in cultivating the family trade; and if it were worked in all sections of the country to the limit of consumption I honestly believe that, with prices 50 per cent higher than at present, there would not be sufficient honey produced to meet the demand.

In seasons of plenty, sell all you can at remunerative prices; but do not sacrifice your

honey and thus lose the legitimate reward of an abundant crop.

In the season of 1908 there was an abundant crop, and some bee-keepers got panicky and sold out at prices barely above the cost of production. The season of 1909 was not so good; and if some of that honey had been carried over it would have brought better prices. This applies with greatest force to extracted honey; but comb honey can also be kept over if care is exercised.

Let every bee-keeper be alert to the fullest possibilities of his chosen occupation, and determined to obtain the legitimate compensation for his skill, toil, and trouble. It is his lot to produce his crop of honey only by the sweat of his brow, and against many pointed attacks by superior numbers (the bees); but remember that, in retailing direct to the consumer, there is little danger of being "stung." Spot cash upon delivery of the goods is the rule, and an increasing demand with advancing prices is the fair prospect.

Kenmore, N. Y.

#### ALEXANDER IMMORTALIZED.

His Methods Defended, and Dr. Miller Criticised for Misapplying His Treatment for European Foul Brood.

BY E. E. PRESSLER.

The article appearing on page 760, Dec. 15, entitled, "Some Discoveries on the Alexander Treatment for European Foul Brood, by Dr. C. C. Miller," and its subsequent comments by the editor, are as discrediting to the teachings and writings of the late lamented Alexander as they are untrue.

While I never wish to pose as a writer, or aim to have my name appear in the bee-journals as a critic, I can not forbear in this case (the author being dead) to enter at least my protest against such juggling of that eminent teacher's writings. The article in question is not only doing gross injustice to his memory, but to every bee-keeper who has ever had European foul brood, and also to his many friends.

I have only the utmost regard for both you and Dr. Miller, and believe that perhaps as many bee-keepers are indebted to you two writers as to the late Alexander. It is not my purpose here to belittle you, if I could, but to defend and support the teachings of one who is no more. Realizing full well that you two "big fellows" are amply qualified to refute any wrongful allegations I might make, I am prepared to crawl into my hole without another word if you should be able to "come back" at me.

If this article in GLEANINGS proves one thing more than another, it is that neither Dr. Miller nor its editor is even familiar with the *literal* knowledge of the Alexander treatment.

Nowhere in all his writings can I find where he speaks of "ten days," "introduc-

ing a laying queen on the twentieth day," nor where he "thought" his cure was efficient for American foul brood. Dr. Miller says, "Mr. Alexander never insisted that his plan would succeed with American foul brood, although I believe he *thought* it might do" (italics are mine). Alexander very emphatically said on this very point, "The old American foul brood is incurable. You can save the bees by the McEvoy treatment, but you can not save the combs." About three years ago, when his plan was attacked, and denounced as not being suitable for American foul brood, you, Mr. Editor, appealed to him to straighten out the muddle, which he did in his almost ante-mortem statement in the following lamentation, taken from page 166, Feb. 1, 1907:

"I do wish I could impress on the minds of all bee-keepers that I never recommended any cure for American foul brood. I wish to have it understood that I don't think that, up to the present time, there has ever been a comb that was affected by American foul brood cured of that disease. You might as soon expect a colony of bees to clean out their combs if filled with paint as to expect them to be able to remove the rotten larvæ. Many bee-keepers are continually speaking and writing of these two diseases as one and the same. Now, if it were not for the young and inexperienced bee-keeper I would not notice this mixing-up of a very important matter. Then when my critics go still further, and speak of the cure I recommended for European foul brood as failing to cure American foul brood, and in that way belittle that cure, when I from the first wrote that I did not think it of any use for American foul brood, they do me injustice. You might as well expect to cure American foul brood by throwing a cup of cold water in the grass in front of your hives as to expect to cure it by requeening as I recommended for European foul brood. The reason why American foul brood has never been cleaned out of a comb is because a larva that dies from that disease is so much like glue that the bees can not remove it in its soft state; and before it dries down it penetrates with its spores into the cocoons of the cell until it becomes a part of the comb itself, where it can not be reached by any disinfectants, nor removed by the bees."

Almost on his dying-bed when he wrote the above, are we now to believe this dying man was trying to deceive us when he lamented in the above language? No, surely not; nor can his words be misinterpreted; they are too plainly understood. There are very many similar expressions throughout his writings, positively showing that he did not think "it might do."

Dr. Miller says the Alexander plan consists of a few words: "Make a colony strong, make it queenless, let it remain so three weeks; then give it a vigorous young laying queen. That's all" (23 words). Can any thing be more falsely represented? Alexander never recommended giving a *laying* queen in less than 27 days. This, the very chief point in

his treatment, is *eggless* for at least 27 days. Dr. Miller overlooks this point entirely as essential. Nowhere in all of Alexander's writings did he ever say that a *laying* queen must be introduced four days prior to the hatching of all the old brood. Now the "sage of Marengo" introduces a *virgin* on the tenth day (one day later than Alexander recommends the destruction of all queen-cells or virgins), which makes it possible for new eggs to be in the hive on the fifteenth day, or nine days before all the old drone brood is hatched. Under normal conditions, colonies made queenless with Dr. Miller's "discoveries" make it possible to have a laying queen in the hive earlier than if they were left to their own fate. I wonder how many of those who read his "modifications" believe the doctor when he says that he discovered that diseased brood piled up over an excluder on top of a strong colony will be cleaned out in "eight or ten days"? In fact, he says "even less time may answer when there is not too much cleaning-up to do."

Now listen: 'Mr. Alexander had hardly gone beyond the experimental stage, and it is possible that he never tried any shorter time than three weeks.' Those who had the honor of knowing Mr. Alexander, know, and know it well, that he would not recommend anything to others that he had not thoroughly worked out for himself, not in one season, not on one colony, not in "eight or ten days," but in every conceivable scientific, methodical, diligent, painstaking, and conscientious way on hundreds of colonies for a period of many years. This is against Dr. Miller's one season of experience with European foul brood.

I have had more than ten continuous years, not alone with my own bees, but with those of others, for whom I did the curing. I have gone over the field pretty thoroughly, and tried the Alexander method for the past three years. I have had several hundred badly diseased combs cleaned out in five days over excluders, but the combs had hung in the honey-house all the previous winter and were condemned for wax, but I had trouble in securing supplies for myself last spring, so I decided to use them again, having no fear whatever, as I knew they could be cleaned. In Dr. Miller's case he placed combs with live brood on top of excluders (presumably to save the brood), and when he says "In about three weeks from the time the pile was formed (21 days from the time of the removal of the queen), the queen was laying in what generally proved to be clean combs." Oh how easy! Would or could the results have been different if the queen-cells had never been destroyed and a "virgin of choice stock" substituted? If this kind of teaching were true, no European foul brood could ever have existed. Nature makes ample provision for just this very thing without the intervention of Dr. Miller. In from eight to sixteen days after the prime natural swarm, nature always introduces a virgin (sometimes of "choice stock").

Alexander is very positive in his instruc-

tions on this point when he says, page 1125, Nov. 1, 1905, "Supply each one of your diseased queenless colonies with a ripe queen-cell or virgin just hatched . . . on the twentieth day after you have removed their old queen, and not one hour sooner, for upon this very point your whole success depends; for your young queen must not commence to lay until three or four days after the last of the old brood is hatched, or 27 days from the time you remove the old queen."

Does this savor of the "experimental stage" from a man who was as honest and thoroughly positive as the firmament?

To my mind it is obvious that in this, his first trip, Dr. Miller did not travel over the Alexander road. How, then, does he know where the mud-holes or bridges are? He made a guess, and says the road is macadamized (easy), and that sewer-pipe was used in construction for the underdrains, and that he has "discovered" a much nicer grade, recommends that less expensive drain-pipes be used, and a crosscut of Wingard's four-mile swamp can be made by supplying stilts for the horses, therefore reducing the distance three miles. I will admit that Dr. Miller is a good guesser in the "bee-line," but on this Alexander road he has another coming.

Mr. Editor, how is Dr. Miller capable of modifying or "discovering" something new in this road, when it is manifestly true that he never traveled it? Is it possible, after paying \$50.00 for this very information in order that the world may profit by it, that you do not know what you bought? After being at his house, and an eye witness to his methods, do you believe Alexander was a fakir and a liar? Your comments are worded in your characteristic adroit and somewhat illusive style; but your headlines and general import are misleading, this being true not only in the articles of Dr. Miller, but with the articles of Alexander. It is mainly through your editorial and comments that this misunderstanding occurs.

After writing the above, in substance, I decided to allow you and Dr. Miller sufficient time to see the error of your way, and you would surely endeavor to retract in the following issue of GLEANINGS; but, alas! no repentance; instead, a continuation of the same standard of teaching. Even if Dr. Miller was correct in his deductions from his very limited experience with European foul brood and the Alexander method of treating it, it is a question if such knowledge is safe in the hands of the average bee-keeper, not considering the amateurs.

In aiming to perpetuate the memory of Alexander, and safeguarding the interests of all bee-keepers, let me suggest that hereafter Dr. Miller's data of any new "discoveries" on any of Alexander's teachings be first submitted to the University of Copenhagen before it be given to the public.

Williamsport, Pa.

We decided to turn our pugnacious correspondent over to the "tender mercies" of Dr. Miller, feeling that if he (or we) were

really "guilty as charged" he would confess; if not, he would fight it out. We decided to have the "fracas" all in one issue, and asked Dr. Miller to reply, which he does.—ED.]

Mr. Pressler is anxious that no injustice shall be done to one who can no longer defend himself. For this I thank him heartily, whether I am guilty or not of having done any injustice to Mr. Alexander. Moreover, if I have in any way made any wrong impression as to the truth about the treatment of foul brood, the man who calls my attention to the wrong does me a friendly turn; so again I thank Mr. Pressler.

I must confess that it comes to me as a great surprise that in writing what I did I should be found doing gross injustice to the memory of Mr. Alexander, for it was my desire and design to give him the fullest credit for having given to bee-keepers his treatment of European foul brood. Certainly, without his teachings I do not think I should have tried any other treatment than throwing the diseased bees upon foundation.

I think, however, that the injustice Mr. Pressler has in mind is not so much—perhaps not at all—trying to withhold any credit due Mr. Alexander as it is misrepresenting his teachings. I am very sure that nothing of that kind was intentional, and I think it quite possible that Mr. Pressler's understanding of the matter comes from having the two treatments mixed—the Alexander treatment and the treatment I used. And right there may be seen the danger of getting into trouble by taking either one of two courses. If I made no attempt to give credit to Mr. Alexander, then some one might say, "That's the Alexander treatment, distorted, to be sure, and the fellow gives no credit for it, trying to palm it off as his own." If I took the other course, which I did take, giving Mr. Alexander full credit, then there is the danger of the understanding that something I have done may be understood as being according to Mr. Alexander's teaching. Well, I'd rather be thought a liar than to be thought both a liar and a thief, so I'm glad I took the course I did.

I beg, however, friend Pressler, that you will not believe me guilty of either of the bad things I have named; but if I have in any way misrepresented, please set it down to the fact that I am not an adept at properly expressing myself (the use of the English language always has bothered me); for I want very much to retain as much as I can of that regard you say you have for me.

And now let us look at the bill of particulars. The first item is "That neither Dr. Miller nor its editor is even familiar with the *literal* knowledge of the Alexander treatment." I am not solicitous about the editor—meaning, of course, the editor of GLEANINGS—for if he isn't guilty of that he is guilty of other things; but I want to plead for myself that at least I have read with very much interest the article by Mr. Alexander in GLEANINGS for 1905, page 1125, which I believed, and still believe, gives correctly the

Alexander treatment for European foul brood. I am willing to say at least this much for the editor: That, as he appended an unusually long footnote, the probability is that he read the article.

You say, friend Pressler, that nowhere in all Mr. Alexander's writings can you find where he speaks of "ten days." Well, nowhere in all my writings do I know of any place where I said any thing about his speaking of ten days. In the article in question, page 760, I speak of ten days four times, but each time as being part of my treatment varying from the Alexander treatment, and the footnote mentions it in the same way.

You say you can't find where he speaks of "introducing a laying queen on the twentieth day." Well, I can't find where I said he spoke of it. But I came so near it that there's no use quibbling about the difference. I gave as the Alexander treatment, page 760, to let the colony be queenless three weeks and then give it a laying queen. And now I have the very humiliating confession to make, that, until I began writing this paragraph, I didn't know that in giving the resumé of the Alexander treatment quoted by you, I had in the least misrepresented the said treatment, and turned to page 1125, 1905, to quote Mr. Alexander's own words about giving a *laying* queen. (I think I had never before given his own words in quotation marks.) What was my amazement to find that, instead of "laying" the word was "virgin"! I had read it over a number of times (twice at least after reading your article), but each time *thinking* "laying" as I read "virgin," discovering my error only when I went to make a direct quotation with the proper quotation marks. Talking it over in the family, one member asked me, with just a touch of reproach in the question, "How did you come to make such a mistake?"

"I don't know," I replied, "do you ever do any thing of the kind?"

"Um-huh," she replied, with her mouth full of pins.

And there you are. It's a queer trick of the mind that I don't suppose I'm at all alone in. I've done it occasionally all my life, and I'm afraid I'll never outgrow it. I can only say that I am exceedingly sorry for the blunder, and express my thanks to you for calling attention to it.

You say you do not find "where he 'thought' his cure was efficient for American foul brood." Neither do I. Nor did I say he thought so. As you put it, it is a positive statement that I knew he thought his cure was efficient. There is some difference between making a positive statement and saying "I believe." There's a very wide difference between saying "I believe he thought his cure was efficient for foul brood" and saying "I believe he thought it *might* be so." I do not at all think that within the next year three cents will buy a bushel of good wheat, but I think it is within the range of possibilities that it might do so.

But I do not believe that you intentionally misrepresented what I had said, for you im-

mediately quote correctly my exact words, which goes to show that I am not the only one who can read a wrong meaning into words; but you can go a step further than I, making the direct quotation without seeing your error, while I saw my error as soon as I thought of making a direct quotation. Well, we're none of us infallible.

I think I was fully warranted in saying "I believe he thought it might do so." On page 1126, GLEANINGS, 1905, the editor says, "The question may naturally arise now, whether or not this Alexander treatment would not prove equally effective in the case of foul brood. We do not know. Mr. Alexander is somewhat doubtful," etc. If he was in any doubt about it, then he thought it might do so, even if there was only one chance in a million.

Very likely you will say, "But what about that article on page 166, 1907, in which Mr. Alexander says he never recommended any cure for foul brood, and from which an extract is given?" I have no recollection of reading that article or the extract from it until now reading it in your article. When I receive GLEANINGS, it is not carelessly read and digested, but hastily crammed to find whether anything in it may be commented on in Straws, the cramming and the writing to be done inside of 24 hours. Afterward there may or may not be careful reading. Evidently that article on page 166 never had close attention until the reading of your article, and so slid from the memory like grains of sand from a surface of glass, while the article on page 1125 with its tootnote was distinctly present when I wrote, "I believe he thought it might do so." I am sorry I didn't know at the time all that Mr. Alexander had written, but I didn't.

As to the matter of the "experimental stage," is the whole subject of European foul brood beyond experiment? Is the Alexander treatment universally accepted? If Mr. Alexander were yet alive, are you sure he would do no further experimenting in this matter?

In giving a resumé of the Alexander treatment, I made the very stupid blunder of putting "laying" for "virgin," and 21 days for 20 days. I think that's all that's wrong in it. I don't know that that one extra day does any great harm; but the other error is exceedingly bad, and I am very, very sorry for it. But in reply to your question, "Can any thing be more falsely represented?" I reply, "Yes; bad as it is, if I were to buckle right down to it I think I could do even worse than that."

On your part, friend Pressler, there are several counts in the indictment against you that must stand unless you can refer to the places where the things are to be found that you quote against me. As two of them are in quotation marks they are supposed to be my exact language, and ought not to be hard to find. If found, my apology is ready.

Don't you think we had both better reform?

C. C. MILLER.

Marengo, Ill.

## THE ALEXANDER METHOD OF TREATING EUROPEAN FOUL BROOD.

### All Depends on Having the Colonies Strong.

BY IRVING GROWER.

In common with many other bee-keepers in central and eastern New York I have had European or black foul brood in my apiary. I have had the inspector of apiaries for our district prescribe treatment which consisted in shaking on foundation in clean hives, melting up the combs, and disinfecting every thing thoroughly. This I did in 1902. The season was poor, and the shaking was more or less a failure, so that the trouble showed up quite prominently again the following spring. I continued the shaking process with varying results for several seasons. One thing which the inspector impressed on my mind was the importance of good Italian stock, and that I should keep all colonies strong. At that time he made the statement that some strains of Italians seem to be immune to the disease. I had been a honey-producer fifteen years before I ever saw the disease, and half or more of my colonies were Italians, the others being all grades of hybrids. Each season I Italianized more of the colonies.

When the Alexander method of treatment was published I pronounced it too good to be true, but at the same time made preparations for trying it, and the following season purchased a breeding queen from one of the noted breeders. Mr. Alexander advised making all the colonies strong, either by giving brood from healthy colonies or by some other plan. Now, any one who has had any experience with disease will hesitate before placing frames of brood from healthy colonies in those that are diseased, so I decided to strengthen these diseased colonies by shaking young bees from five or six frames into each hive which I intended to treat. I then made these colonies queenless, and left them so 21 days. Being busy with other work I did not make an examination until almost time to give the queens that I had reared, and I found that the colonies were not as strong as I thought they were, so I shook in some more bees and introduced the queens. When brood-rearing began to show in the hives the disease was still there except in one or two cases, so of course I voted the treatment a failure.

It was by an accident that I found that, if we wanted to be successful with the Alexander treatment, we simply had to make the colonies strong. The season following my failure I prepared to shake all colonies that showed the disease on to foundation when the honey-flow was nearly at its best. When the time arrived I found that I had eight colonies to treat; and as none of them were strong I decided to select six of them and shake the bees into two clean hives, as there was quite a lot of good brood in the frames, so that there would be enough young bees

to take care of the rest of the brood if it were tiered up.

I intended to shake again on to foundation, giving a queen at the opening of the buckwheat season. This I did, but there were too many combs from the six hives to put over one hive; and as it was nearly dark, and as there were the two other hives which I had not shaken, the queens of which were old and not laying, I decided to give a part of the combs to these two hives, and, after the buckwheat flow was over, to kill the bees, extract the honey, melt up the combs, etc. I used the hive illustrated in "Quinby's New Bee-keeping," called the new Quinby hive. It has 16 closed-end frames. In each of these two hives I filled the lower part and then put 16 more frames on top, making 32 in all. I did not open these colonies until the season was over, and all the colonies were nearly out of brood; and then I found plenty of honey in the hives, and in each were fine young queens. After some consideration I decided not to destroy the colonies, but to pack them for winter. They wintered well, and were the first to swarm the following season, and they did not show a sign of disease, nor have they done so since.

Unconsciously in the above I had done what Mr. Alexander had advised; that is, had made the colonies strong. The natural instinct of the bees to supersede a failing queen caused them to take advantage of the condition, and do it at the time, making the cure complete.

Cooperstown, N. Y.

### EUROPEAN FOUL BROOD.

#### Golden Italians More Immune to it Than the Leather-colored Strains.

BY EDGAR WILLIAMS.

I have read with interest Dr. Miller's account of his experience with foul brood. He said the disease was very mild, most of the cases showing only a few diseased cells. If the colonies had been badly affected I do not believe he would have been as successful.

A few years ago I had thirty colonies, all badly diseased; in most of them over half the brood was affected, and in some of them there was very little healthy brood. I gave all the colonies the McEvoy treatment, and a few days afterward noticed a quantity of matter as large as a bean in front of one of the entrances. Whether this was diseased I can not say; but anyway a good many of the colonies showed signs of trouble shortly after the treatment was given, and by fall all were slightly affected, a few of them being simply rotten with it. The following spring all were badly diseased again. I sent a sample of the brood to Washington, and it was pronounced European foul brood. I tried nearly all the remedies then known—drugs, etc., but nothing gave any help.

I had heard of the Italians being able to

resist disease, so I sent for a dozen queens. The following spring the colonies to which I had introduced these queens were healthy, although there were diseased colonies all around them. Since then, with the pure Italians I have had scarcely any trouble. Some of the leather-colored strains showed the disease quite badly. The goldens are the ones that resist the trouble best, very few of them showing any bad symptoms; and when they do there are never many cells affected, and these are always cleaned up when the honey-flow opens.

In the spring, during the breeding months I look over each colony every week or ten days; and if a few cells of disease are found, that colony is marked; and at the next week's examination, if the trouble is still growing I kill the queen at once. Then in about ten days I give a cell from my select golden stock and the job is done. If the queen is purely mated, such colony is cured; but if she is mated with a black or hybrid drone I generally have my work to do over another year. I have had extra good hybrids, nearly all yellow, that showed the disease as badly as the blacks. It is necessary for the colonies to be pure. As my bees are now nearly all immune to the disease I handle them just as if there were none among them. I once took some combs, nearly half of the brood in which was affected, and gave them to a colony of goldens. In two or three weeks' time these combs were healthy. One fall I had four or five colonies that were so weak with the disease that I knew they would not winter. I sulphured them, and the next spring hived golden swarms on the combs, and the bees remained perfectly healthy.

#### TWO QUESTIONS.

If cappings are rendered in the solar wax-extractor, is the flavor of the honey injured so much that it would be unsalable? The temperature of my bee-cellar this winter has not been above 40 much of the time, and it has been down to freezing once or twice, the general average being about 38 degrees. The bees seem to be wintering well. I have had a fire in the cellar occasionally. Would it do any harm to start the fire with kerosene if I used wood afterward? There is some smell from the burning oil at first.

Pierpont, Ohio.

[Most authorities would consider it very risky to exchange combs promiscuously in a yard where European foul brood existed; but more than one bee-keeper has reported doing this very thing with no apparent bad results, provided the apiary is stocked with golden Italians. Who else can add testimony on this question?

The honey from a solar wax-extractor, unless great care is used, is quite likely to be injured. Most producers drain as much of the honey out of the cappings as possible before putting them into the solar extractor, and in this way the loss is not very great.

We do not believe that there would be any danger of losing bees if kerosene is

used simply to start the fire. However, we think that as little of it should be used as possible. After some practice you can start the fire quickly with a very small amount of oil.—Ed.]

### ANOTHER WHO HAS USED THE ALEXANDER PLAN OF CURING EUROPEAN FOUL BROOD.

BY F. W. LUEBECK.

I do not know what previous experience Dr. Miller has had with European foul brood; but all through his article there is evidence that he must be a new hand with the trouble. If he thinks his bees are now cured he will be sadly disappointed, and next season in May or June he will have another story to tell. During the summer a newly infected colony, or a colony just starting a new brood-nest, will remove all diseased larvæ, and irregular brood or brood of different ages close together is the only evidence of the disease. However, as soon as the bees come again to a state of low vitality, as in the spring, they will not remove the dead larvæ, consequently the disease will make headway very fast. Italians having a vigorous queen will succeed to a certain extent, while the blacks or hybrids will make no effort to clean out the foul matter.

Combs above an excluder, taken from foul broody colonies and given immediately to healthy colonies, will start the disease in a short time; that is, if unsealed brood is present in the healthy colony at the time that such combs of honey are given; but, on the other hand, if the combs are away from the bees for some time there would be no direct infection, as the germs can thrive only in dead animal matter. But it is just possible that some of the cells of honey contain the spores of the germs; then, as soon as such cells are opened and the honey fed to the larvæ, infection is the result.

I tried the Alexander plan on about 50 Italian colonies when they were fairly strong, and when there was not too much dead brood, and perfectly healthy brood has been the result.

Now, it is not my intention to discredit the McEvoy treatment for European foul brood; for when the disease breaks out for the first time, and most of the combs are a mass of dead matter, there is, perhaps, no other way than to remove them; but as soon as possible thereafter, all queens of such colonies should be superseded by those of a more immune and vigorous strain of pure Italians. Hybrids and blacks should not be tolerated under any circumstances in a locality where this disease is present. Nature's object in the disease is to improve the races of bees by destroying and weeding out the weak ones; so if we breed our queens only from the most immune strain, we shall aid nature direct, and the trouble will disappear as our bees improve in vigor and vitality.

It is now four years since my apiaries were struck by this disease. I have 81 colonies at

present, which were all nice and clean last fall, but I believe the disease will appear again next spring. However, I am not worrying much about it, as I have learned to control the trouble without destroying the combs, so that I shall not be obliged to interfere with the gathering of a honey crop.

Knox, Ind.

### PREVENTING ABSCONDING WHEN TREATING FOUL BROOD.

Do the Bees Ever Mix Honey and Foul Brood in the Hive?

BY E. M. GIBSON.

As Dr. Miller has broken the ice I may say a few things in corroboration of what he says on page 728, Dec. 1. From what he has written or from what I may write, if any one gets an idea that foul brood is not a bad disease to combat I can assure him that he will change his mind if he is so unfortunate as to get it among his bees. The doctor says he got desperate because so many colonies were absconding. This could have been avoided by putting a queen-excluder on the bottom-board of the hive in the same manner one would place it between the super and brood-nest, leaving it on three or four days, when the bees would have cells drawn, and honey and eggs in many of them. The excluder could then have been removed without any danger of bees leaving. This, of course, can be done only with interchangeable hives, or, at least, not with hives with the floor nailed on. I did not disinfect or burn out my hives, and did not use lye in the water that I scalded my frames in. Mine was American foul brood.

As to infection being carried into the super, I would say I put eight colonies on to foundation, putting all the combs from the brood-nest into the supers and putting them on top with a queen excluder between them. All the combs put above were more or less infected. I left them until I could not find a cell not filled with honey. I marked hundreds of those infected cells, but never found one with honey until it was thoroughly cleaned out. When the scale was too hard to be removed they invariably tore the cells out and built new ones. I use those combs now.

I have never been able to find honey and scale in the same cell. Has any one? I am curious to know from what source the honey was obtained in which chemists have found foul-brood spores, whether extracted or taken from a well-filled comb. Extracted honey thrown from a diseased comb could not fail to be infected; but with two years' diligent search I have failed to find it mixed in the comb; yet the microscope might show particles too infinitesimal to be seen with the naked eye; but with my present knowledge and experience I would not hesitate to feed back honey taken from the super above a queen-excluder of a diseased colony. Those eight colonies all had to be treated again as I expected.

Jamul, Cal.

## BEE-KEEPING AS SEEN ON A TRIP THROUGH EUROPE.

BY JAS. B. PAIGE.

It was my good fortune during the past summer to travel 3500 or 3600 miles by auto on the Continent and in Great Britain. I was in England, France, Italy, Germany, Switzerland, and Holland. I had with me a small pocket camera, so took advantage of every opportunity to get pictures of interest to bee-keepers. At the suggestion of Dr. Burton N. Gates I am sending a few prints, thinking they may be of use in GLEANINGS.

Fig. 1 shows bees in the Bernese Alps, Switzerland, on the road from Interlaken to Grindelwald. The elevation is 3000 to 4000 feet. There are two rows of "skeps" covered with burlap, in the house which is open, and shingled with pieces of flat stone. In the background are bare mountain-peaks over which the fog "warps" in graceful curves and fantastic shapes, to disappear again in invisible mist. From the field in which the house is located one obtains a most beautiful view of the eternally snow-capped peaks of the Jungfrau (13,670 feet), the Monch (13,468), the Eiger (13,040), besides many

FIG. 1.—BEES IN THE BERNESE ALPS, SWITZERLAND.‡

peaks of equal height, including the Wetterhorn, Schreckhorn, Finsteraarhorn, and Silberhorn, and, in the beautiful valley below, the turbulent, rushing black Lutschine laden with debris from the upper and lower Grindelwald glaciers in transit to Lake Brienz.

Fig. 2 is a Swiss "chalet" in the Lüttschen Thal, near Grindelwald, Bernese Oberland, Switzerland. Six "skeps" covered with burlap sacks are outside the windows of the living-room, protected from rain by the overhanging roof. Note the wood nicely piled beneath the hives. The upper floor is reached by a pair of outside stairs with a landing on the balcony, seen between the windows above, and those near which the "skeps" are standing. The garden at the end of the chalet was filled to overflowing with flowers and vegetables.

In the vicinity of this Swiss home the fields and mountainsides were richly covered with vegetation in which honey-producing flora was abundant. White clover grows here in great profusion, and occasionally one finds sweet clover.

Queer hives in a farmer's garden at Payerne, Switzerland, are shown in Fig. 3. All along the route from Lausanne to Bern, through the rich Boyer Valley,

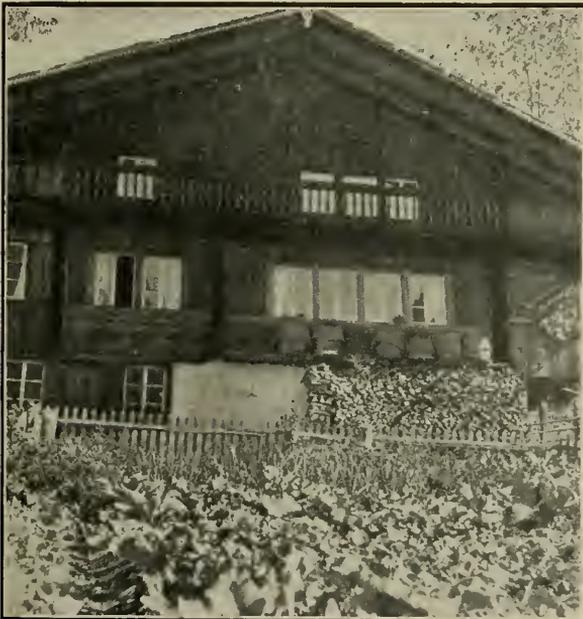

FIG. 2.—SIX "SKEPS" COVERED WITH BURLAP OUTSIDE; A SWISS "CHALET."

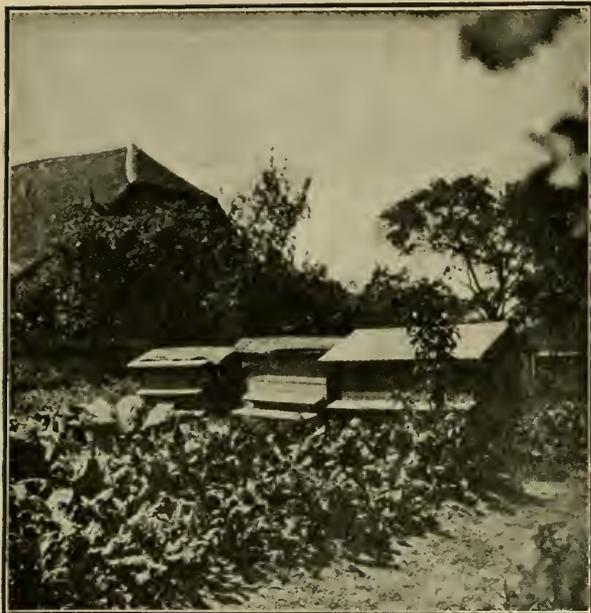

FIG. 3.—BEES IN A FARMER'S GARDEN AT PAYERNE, SWITZERLAND.

many hives of bees are seen about the homes of the farmers. Most commonly the "skep" is seen, but occasionally one notices a modern movable-frame hive. The style of hive shown in the picture is rare. It was, indeed, a wonder. Consisting of a long case, the back part of the roof hinged to open, it contained three sets of movable frames, and had sufficient space above for three sets of one-pound sections. The sets of frames and sections were placed end to end without partitions between them. After a spirited speechless sign conversation carried on with the farmer and his "frau," I was permitted to view the interior of the hive in the foreground and to take a picture of the yard. The bees were of the black variety, and decidedly energetic, so that my investigation was neither thorough nor protracted, and I am unable to state whether there were multiple queens present or not.

Fig 4 is an apiary near Arnhem, in Holland. The shed is covered with tile. The "skeps" have openings above the middle. Usually the skep super is made of straw, being a miniature hive, but in some instances supers of wood are used, and it is not unusual to find skeps tanding in the gardens cover-

ed with large red earthen bowls to protect them from the rain and heat.

Black bees, a warm day, and a hot time in getting the pictures are my recollections of this apiary.

Amherst, Mass.

#### HIVE-STANDS.

**How the Ideal Foundation for a Hive Should be Built; the Value of Concrete Slabs under the Regular Stands.**

BY F. GREINER.

Judging by the many fine illustrations of bee-yards in the different bee journals, for example on pages 772, 773, Dec. 15, the hive-stands often employed have some grave faults. Even our good Dr. Miller, according to his own words, makes use of a very poor affair. A hive-stand alone may be considered an insignificant factor in honey production; but it is my opinion that a good one may at times increase the yield from the apiary materially. It may save valuable time to the bees; it may prevent loss of bees and sometimes even of queens. A good hive-stand should, according to my views, embody certain principles of which some seem to have

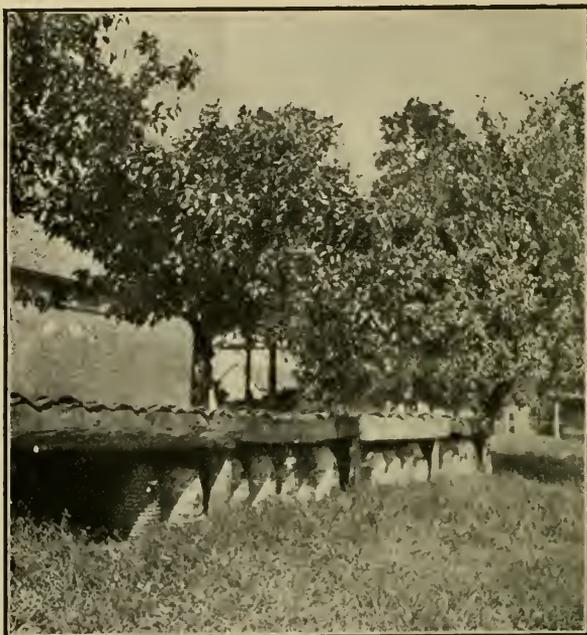

FIG. 4.—AN APIARY OF STRAW SKEPS NEAR ARNHEM, HOLLAND.

HIVE-STANDS PROPERLY CONSTRUCTED, AS USED BY F. GREINER, NAPLES, N. Y.

been lost sight of. Foremost, it should assist the bees in gaining their hive-entrance safely. When A. I. Root introduced his Simplicity hive forty years ago he advised the use of four bricks for the hive to stand on, with a heap of sawdust piled up in front of it. Many of us tried this. The sawdust kept down the grass and formed a passageway from the ground up to the hive; and although it seemed to be agreeable to the bees, it had some unpleasant features, like blowing into the hive when dry, rotting the hive when wet, and then the grass crept over it and filled it full of roots, etc. An unplanned board is almost as acceptable to the bees, and is much more reliable. I believe the use of sawdust has entirely gone out of fashion, and the pine board has generally been adopted for an alighting-board. I theorize that it is better than cement on account of being a better non-conductor of heat, but, of course, it is not as lasting.

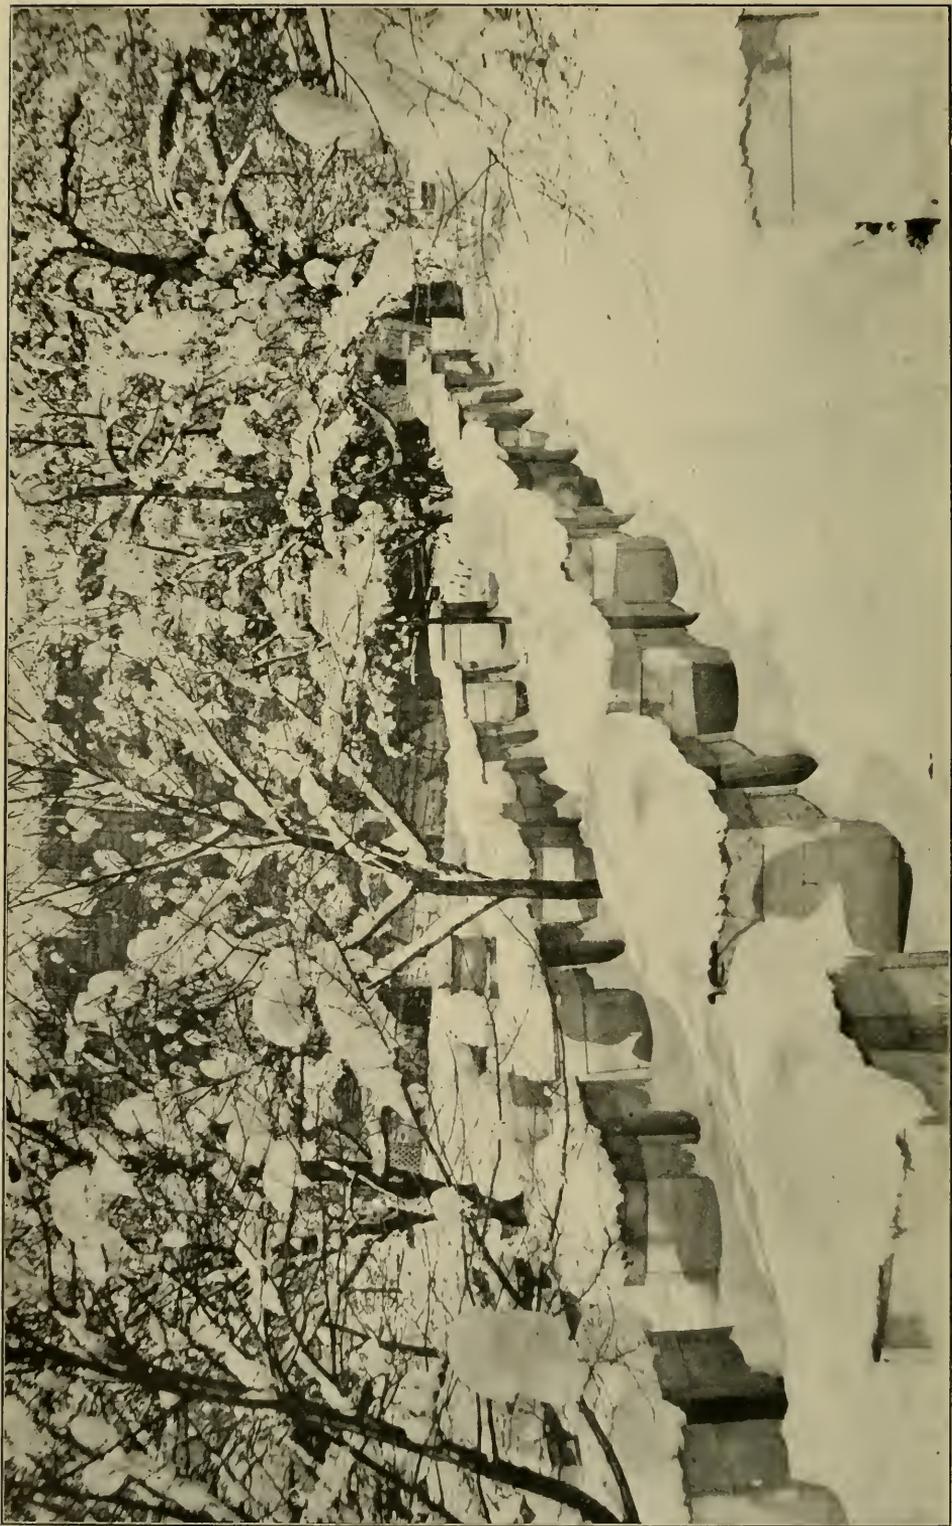

The hive-stand should be close fitting to the hive all around. It should not furnish an opportunity for bees to cluster under the hive nor afford a hiding-place for toads during daytime. These ugly fellows are very objectionable visitors in the apiary, and eat a great many bees when they can get them. As the toad is very useful in other ways I never kill one; but when I find one around my hives I carry it away a long distance; but by not allowing harboring-places for them under and among the hives, very few of these animals stay around.

The easiest way to make every thing snug

is to make a shallow box of the same size as the hive bottom, making the front end slanting and tight-fitting against the hive. There should be no holes left anywhere for bees to enter the space under the hive. I have known bees to set up housekeeping under the hive, totally ignoring all the new-fangled fixtures which we had put inside, just because the hive proper was not well guarded.

A hive-stand should preserve the least amount of actual contact between the hive-bottom and the stand. At one time we were using a hive-stand which consisted of a platform made of common lumber, somewhat larger than the hive-bottom, and nailed upon two pieces of scantling. As Dr. Miller says, this is the poorest thing one can use. Between the two thicknesses of lumber moisture collects, and soon both hive and stand rot out. Ants establish themselves here, and perforate the timber. Other disadvantages I need not mention. The shallow box outlined above presents only the edges of the boards upon which the hive-bottom rests; and there being no chance for moisture to collect it will last about as long as any other part of the hive.

The only weak point of the hive-stand described is its readiness to rot away. As I make them they are five inches deep; but after ten years' use almost nothing is left, and a new one has to be substituted. The cost, however, is slight, as but a small amount of inferior lumber is required to make one. Dealers offer this hive-stand at 12 cents each, which is as cheap as I can get them out myself.

F. GREINER'S APIARY, NAPLES, N. Y., IN MID-WINTER.

I make them of rough lumber. They last as well unpainted as painted.

It would be an improvement, and enhance the lasting qualities of the hive-stand, as well as make things very neat and tidy, if a cement slab were put down first and the stand placed on it. I am planning to lay out my home yard carefully, making exact measurements: dig the sod off for a space 2½ to 3 inches larger all around than the stand will occupy, filling the space with cement even with the lawn. It is a very pleasing sight to have nicely painted white hives stand out on a well-kept green lawn. I want the lawn at all hazards, but have found that it requires a good deal of handwork to keep the grass down next to the hive where the lawn-mower does not cut. Somehow, and for good reasons, the stools of grass make their heaviest growth right here where only the pocket-knife or shears can be applied. This very annoying feature I expect to eliminate by the cement margin around the hive. A few bee-keepers are situated so as to keep a few sheep in their enclosed bee-yard; and, indeed, the sheep keep down all vegetable growth nicely; but even this best of all methods is open to some objections.

The photo which accompanies this shows my hive-stand as it has been used on different styles of hives in my yards for more than 25 years. The alighting-board as shown is painted white in order to make a better contrast with the surrounding green grass. In reality I do not paint them. If I were to use paint on the smooth surface of the board I would sprinkle sand on the paint while still green. Even a weakened bee would then never "slip" nor lose its foothold.

Naples, N. Y.

[There is one point in favor of a hive-stand with slanting board front which our correspondent has not touched, or at least only incidentally. In early spring, especially after long confinement, bees will often venture out when the sun shines brightly, notwithstanding it is a little too cool for them to remain out long. They will make a few circles, void their fæces, and return to their hives, or attempt to do so, in a more or less chilled condition. Many of them will alight on the ground; and if the approach to the hive is difficult or slippery, some will be lost and never get into the hive; whereas an easier approach, like that shown in the illustration, will induce the bees to go into the hive.

While we do not necessarily lose bees that are chilled outside, yet unless a warming day comes up in the next four or five days or a week, these bees will die. If a temperature of 70 degrees with warm sunshine comes on within the period named, most if not all the chilled bees will "come to" and enter the hive. Even then an easy approach is quite important.

Some years ago our Mr. F. J. Wardell, then in charge of our home yard, called attention to the fact that those colonies not supplied with slanting-front entrances showed a greater spring dwindling than those that were

so supplied. The reason was quite obvious when we began to look at the number of dead in front of the hives having vertical-front entrances.

This is a matter of considerable importance, and our readers should take note of the comparative mortality in front of their hives.—ED.]

## THE GROWING OF BUCKWHEAT FOR GRAIN AND HONEY.

### How to Prepare the Soil; the Old-fashioned Black Buckwheat Better for Honey.

BY J. H. M'GOWAN.

I send a snap shot of a buckwheat-field in full bloom. The growing of this crop here is considered by some an uncertainty, while others call it a "sorry crop;" that is, they are sorry when it is good that they did not sow more, and sorry, when it is bad they sowed so much. But in this article I will try to tell how one may be almost sure of getting plenty of bloom (what the bee-keeper likes to see) and plenty of straw and grain.

#### KIND OF SOIL.

To grow this crop to its best, several things must be taken into consideration. First, the soil. Any kind of well-drained land will answer. Buckwheat will not grow on ground that is wet and heavy or where the water stands and gradually dries up, leaving the soil in a hard, lifeless condition. It does best where the land is naturally dry, or made so by proper draining.

#### PLOWING AND PREPARING THE LAND.

Here in Butler Co. we begin to plow just as soon as corn is planted—about May 25. Each day's plowing is rolled or dragged down in the evening. This is important, as one should keep in the soil all the moisture that is already there. We follow this plan until plowing is all done.

#### HARROWING AND SEEDING.

Now, then, the work is only partly done, as it is necessary to keep after this field with a good spring-tooth harrow or disk and roller alternately until seeding time, when the seed-bed should be perfectly clean, fine, and solid. It is now ready to drill in (never broadcast), provided the proper time is at hand. Here we drill from July 1 to 20. *Early* sowing insures a large yield of straw and bloom, while *late* sowing usually fills the best, as the sun is then not nearly so hot during the time of bloom. I have seen fields sown early turn brown in two days on account of the hot sun.

#### HOW MUCH SEED TO SOW PER ACRE.

One and a half bushels Japanese, and one bushel of silverhull or little black is about right. In the Japanese variety the grain is larger and the stalk does not branch out so much as the other two varieties mentioned. This is the reason why more Japanese should be sown per acre; but if *honey* is a consider-

M'GOWAN'S BUCKWHEAT IN FULL BLOOM IN BUTLER CO., PA.

Mr. McGowan, by a close study of the details, prevents failures and makes the crop a very reliable one.

ation I would advise sowing the little black or silverhull, as it blooms until cut or killed by frost.

#### THE USE OF FERTILIZER.

There is another important factor in the raising of this crop; and that is the use of fertilizer. We never think of growing it without using from 100 to 150 lbs. per acre of acid fertilizer, costing from \$10 00 to \$12.00 per ton. It just seems to make it boom—makes both grain and straw, and a much larger yield. Last year I sowed three fields to buckwheat. The first one was drilled in July 6; the straw was medium, and yielded 16 bushels per acre. The second was drilled in July 11; straw heavier than that in the first field, and yielded 22 bushels per acre. The third was drilled in July 19, straw like the first field, but yielded 25 bushels per acre. As a rule, early sowing gives large straw and a poor yield in bushels, while late sowing is the opposite.

Here buckwheat is grown for the following reasons: It comes quick; is easily harvested; is a splendid bee pasture; in fact, it is all we have to depend on. The straw is valuable on the farm. The flour has a ready sale at good prices on account of its national reputation. Nothing is quite so good as buckwheat for poultry; and when ground in connection with corn and oats it makes the best kind of feed for milch cows.

I would urge every bee-keeper, if at all possible, to put in at least a few acres for the

bees, and to furnish some of those good warm cakes which we all like for breakfast. Prospect, Pa.

[We consider this article one of the best and most comprehensive we have ever received. Buckwheat is nearly always a paying crop, particularly as it enables the intelligent farmer to secure a double investment out of his land: As buckwheat pancakes are becoming more and more popular, good prices are usually obtained for the grain. It will, therefore, behoove the bee-keeper farmer, if he has not had much experience in growing this crop to give this article more than a mere passing attention.

What our correspondent says about black buckwheat being better for *honey* seems to confirm our experience. Has any one else noticed the same thing? The question of the kind of seed a bee keeper should sow is an important one to consider, and we hope our friends in York State, where so much buckwheat is grown, will not be slow to respond.—ED.]

#### THE LONGEVITY OF QUEENS RAISED BY BREEDERS.

BY F. DUNDAS TODD.

In the literature of bee-keeping much space is devoted to the problems that surround the purchase of queens from breeders and their introduction to hives in the apiary. The

transportation of the bees is generally viewed as practically solved; and once the queen has been accepted and eggs have been laid, the whole transaction is usually considered as being complete. Only once have I seen a questioning note—the writer hinting that one shouldn't halloo until a few months have elapsed, for supersedure was not infrequent. Since little in the way of definite facts has appeared on this subject it may be interesting to put my own experiences on record, even if my bee-keeping career is a short one.

In my first season (I lived then in Illinois) I bought two queens from a breeder in Kentucky. They arrived safely, and were introduced without difficulty. They were alive in mid-summer, the next year, when I disposed of my hives. In July, 1903, after the honey-flow was over in this part of the world, with but little pickings in the fall, I received from a breeder in Ohio five queens, all of which were safely introduced, and were alive at the end of August, when the last examination of hives was made. One of them was killed by starvation in January; the others died of spring dwindling.

On August 24 I received a dozen queens from the Kentucky breeder, and introduced all of them, apparently with success. The hives were not opened again after the cages were removed until the end of January, when indications of starvation forced investigation. I found four dead with plenty of bees; three died of spring dwindling, and five were alive at the end of the honey-dew flow—honey-flow did not happen—of 1909. Apparently there had been no attempts at supersedure.

Early in April, 1909, I bought a lot of hives in moderate condition; and, being anxious for increase, I ordered from a breeder in Texas a dozen queens. There, as here, had been a pollen-dearth, so my order did not arrive until May 12, and it happened to be one short. One queen was in poor condition on arrival. The day was cold and rainy; and so, choosing the lesser of two evils, I gave the cage to a queenless hive, but the queen was found dead after a few days.

Nuclei were formed for all the others, consisting of three or four Gallup frames of sealed brood and adhering bees. All were accepted and started to lay. One hive showed eggs in 6 days; one in 7 days; two in 9 days; one in 11 days; two in 12 days; two in 13 days; one something over ten days.

A week after introduction we had a killing frost on three successive nights, that play-havoc with the fruit-blossoms. Nectar and

pollen had been coming in freely; in fact, one hive with a fine reputation had hardly an empty cell, all being full of brood or stores, notwithstanding I had robbed it of a frame of stores at three different times to aid weaker colonies. On the 22d I started to feed all hives having young queens; later I did the same wherever needed. I feel it necessary to mention these facts in view of later developments.

When once the queen started laying, the frames were filled solid with brood: the queen that started on the sixth day was prompt about her business. The moment the cells were vacant she filled them again; combs were built; and, long before any of the others were making a good showing, she had one division full; and then, just as promptly, filled another. In just six weeks her bees had built 16 combs and had them filled with brood and honey-dew. Two months later the colony was strong with about 18 lbs. of stores on hand. I consider her record excellent.

The one that started in seven days, on June 17 was doing finely, so I added above it the frames from another hive where the queen had died. July 2 I found queen-cells in the hive but no queen, so supersedure occurred in about 42 days from the laying of the first egg.

Coming now to the queens that began to lay in the ninth day after introduction, one developed a good colony with lots of stores; but the other showed queen-cells in 25 days from the laying of the first egg.

The queen that started laying on the eleventh day was alive at the end of the season.

The two that began to lay on the twelfth day did fairly well.

One of the queens that started on the thirteenth day died suddenly after filling the frames, as, twenty days later, she was missing, and no queen-cells were in evidence. The other is credited as being in fair condition 34 days after the first egg; but 15 days later the hive was found without brood and with an open queen-cell.

The record of the tenth queen is not perfect. She was seen ten days after introduction, but no eggs were in the frames. Thirty days later she was missing, and cells started.

The twelfth queen or the dozen arrived June 20, and was given to three frames of

brood. She was alive at the end of August.

Of the old queens in my purchase, seven were superseded by the bees; but only one of these was superseded in turn. Four

"A GOOD FIND." BROKEN BRICKS FOR HIVE-STANDS.  
See Bee-keeping in the Southwest, last issue.

were superseded in May, from the 3d to the 25th; three in June, from the 2d to the 18th.

Summing up I find that, out of a dozen queens received this summer, one, in evidently poor condition, died in a few days, and five were superseded by the bees in an average of 34 days from the date of arrival. Sometimes I am tempted to lay the blame for the result on the stoppage of nectar for about ten days and the entire absence of a honey-flow, for such conditions must have been exceedingly disheartening to the bees; but, on the other hand, there is an evident relationship between the time of starting to lay and supersedure; for the three that started last of all were included in the list of missing. The one that began on the seventh day was also superseded; but her case is complicated by the addition of queenless bees from another hive, so that the evidence here is not direct.

Seemingly the most vigorous queens recovered the quickest from the seven days' journey; the others may have been injured in the mails.

In keeping scientific records, nothing is considered too trivial for notice; and I am blaming myself for omitting to jot down one point. The eleven queens arrived in two different sizes of cages—the only one that looked poorly being in one of the ordinary small size, and she was the top one at that. I now wish that I had entered on my notebook, opposite each queen, the size of cage she had been received in, for it is possible such a direct comparison might be of value to queen-breeders when filling orders to a customer a week's journey away.

Victoria, B. C., Oct. 1, 1909.

---

### THE CONTROL OF BEE-PASTURAGE.

**Has the Bee-keeper a So-called Moral Right to his Territory? Bee-keeping in the Same Class with Many Other Occupations.**

BY R. L. TAYLOR.

It seems from articles appearing in the apian journals from time to time that there is a growing uneasiness in certain quarters as to the stability of the business of apiculture on account of the fact, as it is asserted, that the bee-keeper has no legal protection in the exclusive enjoyment of his territory, being in that respect at a disadvantage as compared with those engaged in other kinds of business. So we find the assertion that "if ever bee-keeping is to stand on a firm basis like other lines of business, there must be such a condition of affairs that the bee-keeper shall feel just as secure against interference as the stock-raiser who is assured by the law that his fields shall be occupied by his cattle and by his alone." And this: "No bee-keeper in this land has a legal right to his territory."

It would indeed be a deplorable situation if the law discriminates between the rights

to bee-pasture and the rights to cow-pasture. It would be not only alarming but actually disgraceful if, in the eye of the law, bee-keeping did not "stand upon a firm basis like other lines of business." And it would be alike unfortunate, if it were a fact, that "no bee-keeper in this land has a legal right to his territory"—that is, if he has desired such legal right and has been willing to make the necessary sacrifice to secure that right—a sacrifice similar to that which the dairyman must make in order to secure a legal right to his "cow-pasture."

That we may see more clearly whether the law discriminates unjustly against bee-keeping as compared with other kinds of business, let me make use of a few illustrations; and if I should introduce, here and there, some brief arguments on side issues, I trust they may not be found altogether impertinent.

As much dependence has heretofore been placed, in this discussion, on the security the law spreads over the cow-pasture, in order to determine how much reliance can safely be placed upon it, I will take a supposed case in which that pasture largely figures: I collect a small herd of cows and other cattle, and transfer them to a pleasant valley, say in Montana, containing 50 or more square miles of fertile prairie, which, as yet, is all government land. For a few years all is prosperity; my herds increase and begin to try the capacity of the valley. About that time the outside world learns of the beauty and fertility of the land, and begins to crowd in and preempt the territory, starting herds of their own, and press my herds back into inadequate and unprofitable limits. Ought I now to become frantic and proclaim to the world the instability of the basis upon which cow-pasture stands, seeking to arouse the sympathy of the country to the end that the legislature may be invoked to spread the ægis of the law over my cow-pasture? But, unfortunately, I am not a "stock-raiser who is assured by the law that his fields shall be occupied by his cattle and by his alone." Why? Clearly because I have not been willing to make the sacrifice necessary to put myself under the protection of the law.

It may be said that this is not a parallel case because I have no moral right, while the prior bee-keeper *has* a moral right. I freely admit I have no moral right; and as to the average bee-keeper, I am unable to perceive wherein his moral right is any more in evidence than is mine. I make bold to say he *has* no moral right. If my neighbor on the adjoining farm should decide to embark in apiculture, and should start in the business with one hundred colonies I could freely bid him God-speed. For thirty years I have been trying "to learn how many colonies my locality will bear, and I don't know yet." Why, then, should I play dog in the manger? There may be abundance of room for both; and besides, his right, morally and legally, is as good as mine. The most I could do would be to warn him that there might be danger in placing so many colonies in prac-

tically one location that the business might become unprofitable to us both.

But it may be said again that this is not a parallel case because I should have purchased the land I needed for pasture as other stockmen do. This inequality is probably not so great as it appears on first blush; but let us take another illustration:

There are in my little town at least seven shops devoted to the sale of groceries alone, comparatively few of them doing a really satisfactory business; in other words the territory is overstocked. Some of these grocers were on the ground doing business before the others appeared on the scene; but I do not, however, hear any talk of "priority rights" nor of "moral rights," nor of invoking the law to give them exclusive right to territory. Why do I not hear these things? The need is pressing—much more pressing than in the case of the business of bee-keeping.

There is one way in which one or two or more could have secured the exclusive right to sell groceries in this territory, and that is by obligating every owner of land in the district, by making a satisfactory payment, not to allow the sale of groceries on his land, and to bind all subsequent purchasers of the land to the observance of that obligation by the insertion of the requisite stipulation in the deeds of sale.

If you want to secure the exclusive right to the bee-pasturage of a township, for instance, take the course indicated as the proper and effective one in the case of the grocer. There is no other way. Subject to the government's right of "eminent domain," he who has a fee simple in land owns it clear through, from heaven above to hell beneath, and you can not dispossess him of the right to keep bees there, without his consent, short of a constitutional revolution.

But in the case of bee-keeping, unlike the case of the grocer, there is, fortunately, no such pressing need of a resort to some new and unheard-of method to relieve the congestion. With the grocer, practically all choice locations are occupied; but with the bee-keepers, the frontiers of the bee-pasture are only touched as yet. There is, therefore, no present cause for alarm. There is no occasion for crowding, and there will be no crowding that is more than temporary, for the good reason that no one prefers the unprofitable to the profitable. Let us thank the blessed sting and the wide pasture, and be content.

To recur to the cows, we may safely say, then, that there is no good reason why "a man who makes his living from bees, or part of his living, should not feel just as secure in his field as the man who makes his livings from cows" except this: The man who keeps cows is generally compelled (or at least is generally willing) to purchase a right to his pasture, while the man who keeps bees thinks he has or ought to have a right to his pasture without giving an equivalent.

It is not so long since that stockmen undertook to pursue their industry out west on

the plains without securing a legal right to their pasture. They did not always get along as swimmingly as bee-keepers do; but I do not recall that any of them were so lost to reason that they invoked the higher powers to grant them an exclusive right to their territory without expecting to render an equivalent.

Yes, suppose Jones has found a favorable locality and starts an apiary there; and I, thinking the locality not sufficiently stocked, "plant 50 colonies right beside him. Pretty rough on Jones." But that is not a situation peculiar to apiculture, as we have already seen.

Notwithstanding the uneasiness manifested regarding the status of bee-keeping it would be somewhat difficult to make much of a list of those pursuing other occupations who stand in less need of an exclusive right to their territory, either for the production or the sale of their merchandise, than does the bee-keeper; and though there may be some who will be inclined to question the validity of my suggestion that the desirability of an exclusive right to territory for the sale of a product is as important as is the exclusive right to territory for its production, I shall for the present take my position for granted, and make use of one more illustration that may aid in the understanding of the whole matter.

Many years ago I planted several acres of table grapes—the choicest kinds that can be made to succeed here—sufficient to produce all the grapes that my town can be made to absorb profitably. Several others in my neighborhood, seeing my success, and thinking there was good easy money in the business, embarked in it; and, there not being an outlet for the fruit, they overstocked my territory. Then it became a question of the survival of the fittest. Some one had to quit. It was not I.

Not to enlarge upon the theme, must we not conclude that in general, as things now go, the law of the survival of the fittest must govern, and that bee-keeping stands on as firm a basis as other lines of business, even having the advantage in point of stability, and that every bee-keeper in this land may have a legal right to his territory if he is willing to pay the price?

Lapeer, Mich., Jan. 28.

## THE CONTROL OF BEE TERRITORY.

Should a Bee-keeper have a Legal Right to a Territory? has he Already a Moral Right?

BY R. F. HOLTERMANN.

This subject has been taken up by Dr. Miller, page 41, Jan. 15, and I must confess that I admire his courage. He has tried to defend his ground by propounding some questions. Now, this part of it is very easy; but on greater deliberation, possibly these questions may not stand investigation. Let me say, how-

ever, that, like Dr. Miller, I wish very much that we might control certain territories, although the question of overstocking has never given me any sleepless nights. To compare a cow pasture to a bee pasture seems to me like comparing a man's money in a bank to the fish that swim up and down a navigable stream which is owned by the people (the country), but in which fishing can be carried on without restriction. The money in the bank the man owns in fee simple; the fishing privilege costs him nothing; but, according to the measure of his success, so the danger of others benefiting by his discovery increases. It is now about two years since I pointed out that one is rather partial toward apiculture if he says a territory belongs to a bee-keeper because he first located there with his bees. But if the visits of bees to blossoms are a good thing, and if a large number of bees in a section insures a greater yield of clover seed, alfalfa seed, buckwheat, fruit, etc. (and surely it does one year with another), then more than the interests of the bee-keeper must be considered. Not alone is the quantity of the crop greater, but recent experiments have shown that the seed, owing to cross-fertilization instead of continued inbreeding, is more vigorous; in fact, it is probably no Utopian dream to look forward to a time when seeds will have a higher value on account of the cross-fertilization being assured by reason of the apiaries in the vicinity, resulting in greater vigor and strength of the plants raised from that seed.

We as bee-keepers can not agree on nor give conclusive data concerning what constitutes overstocking; much less are we able to decide on the number of colonies (or, rather, bees, for colonies vary much in strength), which under any condition will be sufficient for a good quantity and quality of seed in a given locality. Now, since this is true, what legislative body, acting judiciously and intelligently, could pass a law on the subject? If any one is bold enough to say that this could be done, then I am sure that the editor and all the readers will gladly give him space to declare himself and to submit his evidence.

I already feel quite sure that the limit of profit to the bee-keeper, when the question of overstocking is concerned, is by no means the limit of advantage to the grower of the crops above mentioned. What I mean is that, when there are too many bees kept in a district for the bee keeper to secure the maximum amount of honey, it would still, at times, be to the advantage of the crop-growers to have even *more* bees; and, in the framing of a law, surely the crop-growers must be considered.

As I stated before when referring to this subject, we want to have our cake and also eat it. In other words, so far as it suits me I want to lay claims to the blessing that the bees are to the growers of certain crops, and yet to suit my own ends I should have to ignore that phase of the matter in determining this question of overstocking. The grow-

ers should not be allowed to keep more than a certain number of colonies, nor should they be allowed to reach the limit of benefit to their crops. This all proves to me that, difficult as the question is of solution from the bee-keeper's standpoint alone, from the grower's standpoint already indicated it is still more difficult and the moral aspect more complicated.

Now let us turn to the solution of the problem from the standpoint of bee-keepers only. I know of men, situated in excellent localities, who have perhaps ten, twenty, or twenty-five colonies, and who think that no one else should locate within a mile of their yard, or even several miles; in fact, there is a case just now that has come to my knowledge of a man who has only four or five colonies of bees, and who grows fruit and alsike clover. This party was annoyed because a bee-keeper put an apiary near him, although the other farmers about wanted the apiary on account of the fertilizing which the bees would do to the blossoms in the vicinity. This shows that the estimate of any one man as to what constitutes overstocking may be very far from correct.

Another bee keeper within a half-mile radius purchased at different times over one hundred colonies of bees, and entirely bought out the other bee-men. Some think that this man has man has no right in that locality because he does not live there.

A bee keeper for six or more years has moved to a given locality to get the benefit from a certain honey-flow. When he first moved in, another man a mile away kept about fifty colonies. This last party produced comb honey entirely, and he also hunted and fished parts of the year, thus making his living. Now, he lost nothing by reason of the first man moving in, for he became quite a large producer of extracted honey, and has gained enough confidence in the business to increase his apiary to over one hundred colonies. He is an honorable man, and yet he thinks that the first bee-keeper who was in the habit of moving his bees in for the particular honey-flow, and who had done so all the other years, should now, owing to changed conditions, move away, and that in not doing so he is not acting the part of a consistent Christian.

One more illustration: A man I know has lived and kept bees near a certain city for over twenty years. About a mile from his last apiary a farmer has gradually increased his bees until he has over one hundred colonies. The farmer, too, has kept bees for nearly twenty years. Last year the first man moved all his bees away, yet retained his bee-house and ground for the apiary. The farmer helped him move, expecting to have the location more to himself. Now a third party, whose duties necessitate his presence in the city every working day, has located one hundred colonies about a mile from the farmer. He probably would not have done this had not the first bee-keeper moved away. Now what would you do, Dr. Miller, in a case of this kind? and what would hap-

pen if the first bee-keeper should bring his bees back so that all three would be located there, together with a number of other colonies in smaller apiaries in the vicinity? I am sure if you heard of all the complications that would develop in the history of this instance you would be obliged to scratch your head and say, "I don't know."

To me this is merely one of many other big questions which will not be set right until He will rule whose right it is to rule, and who will have the power and the wisdom to decide these matters justly. Bee-keeping is not the only business in which there are problems of this kind. Laws have been framed in the effort to solve some of them, but they have been dismal failures.

Brantford, Ontario, Can.

## OF WHAT DOES A BEE-KEEPER'S TERRITORY CONSIST?

BY WM. M. WHITNEY.

My apology for this intrusion is the fear that our esteemed Dr. Miller misapprehends, in a measure, my meaning respecting a matter about which he and I entertain a difference of opinion. On page 41 he says: "There are some good men too, like W. M. Whitney, who think that any man has a right to plant an apiary wherever he can get enough square rods of ground for its occupation, without any regard to surrounding bee-keepers." The doctor (for his purpose) puts the matter very ingeniously in the above statement.

Now, I wish to make myself clearly understood, without going into a lengthy discussion of the question of prior rights of individuals to territory. I am very sorry that there are even a few "good men too" like Dr. Miller who think some men have the right to plant an apiary wherever they can get enough square rods of ground for its occupation, without any regard to the rights of the surrounding owners of the broad acres which produce the flowers from which the nectar is obtained.

The doctor says: "Just keep this in mind: *No bee-keeper in this land has a legal right to his bee territory. The fact is, he has no bee territory excepting the ground his bee-hives stand on.*" You know laws are so unconstitutional lately that I'm at a loss to know how an act could be framed that would go through the courts without being made hash of. Perhaps the doctor does. What I claim is, that an apiarist has no moral right (and I'm quite sure he'll never acquire a legal one) to the exclusive use of territory. An apiarist has no more moral right to the control of the surrounding territory for the production of honey than has the man who starts a strawberry-patch from which he hopes to supply his neighbors with strawberries. Now, honestly, has he? Both are working for the same end—a living.

If the doctor and I could join forces and get up some scheme that would work, say, to control the territory each way from our

apiary the distance a bee is estimated to forage for supplies, i. e., about 2½ miles, giving us a diameter of 5 miles; or, in other words, a territory 15 miles in circumference, we would have a cinch. Not only would we control all the blossoms within our boundary, but all the swarms of bees that come through the air and clustered therein would be ours; for no one else would have the right to have them. We might paraphrase the lines of Robinson Crusoe thus:

We are monarchs of all we survey,  
Our right there is none to deny;  
From our apiary, for miles away,  
We are lords of the earth and the sky.

"But," says one, peering over my shoulder as I write, "hold on a little bit; don't get excited over this matter. It may not be so big a thing as you think, after all. Aren't you afraid that you are planning a monopoly in restraint of trade? And won't you become liable to prosecution for violation of the anti-trust law?" Hadn't thought of that. Just think of two such fellows as the doctor and myself and "good men too" getting into such a mixup as that! The smile on the doctor's face, "and one that never comes off," might get him out of the dilemma; but I'd have to go to jail sure. I'd go a long way to accommodate you, doctor; but the more I think about this matter the more I feel like shying at the whole thing. Please consider me out.

Batavia, Ill.

## FOUL BROOD AND DIVISIBLE-BROOD-CHAMBER HIVES.

Can the Disease be Treated in Such Hives without Handling Frames? the Baldridge Plan.

BY J. E. HAND.

*Mr. Editor:*—I have had it in mind for some time to call your attention to a particular point in an editorial in GLEANINGS, July 1, 1909, page 389, on how to select a hive; but the state of my health would not permit until now. It is so seldom that one finds any thing to criticize in your excellent editorials that I deem it a luxury that I feel sure your generosity will not allow you to forbid.

From your standpoint (that of the supplier) I agree with you that it would not be good policy for you to recommend any particular hive or frame to every one, for some might misconstrue your motive, even to accusing you wrongfully of mercenary motives.

In the editorial mentioned, you set forth in a fair and impartial manner the good points of the different hives, and then calmly and deliberately proceed to annihilate the sectional hive in a most complete manner. Your statement that if foul brood were likely to break out in an apiary the sectional-hive proposition would be a fright, for it is not one that will permit of the handling of all its frames with economy of labor, is equivalent to saying that it is necessary to handle all the frames in a hive in order to treat successfully foul brood, which is far from the

truth; indeed, I regard the methods that require the handling of frames in the treatment of contagious brood diseases as unscientific, bungling, and not at all in keeping with modern methods of apiculture. The infection is carried in the honey; and if a diseased colony is disturbed, as in shaking, brushing, or handling frames the bees will fill their sacs with diseased honey which is carried into the new hive, often necessitating a *second* treatment, and *always* necessitating the building of new combs without any help from foundation, which seals the fate of that colony so far as the hopes of a crop of surplus honey are concerned.

I regard the Baldrige method\* as the most scientific, economical, and practical scheme that has ever been made public for the successful treatment of foul brood. By this method the bees have the diseased hive in a normal condition, with empty sacs, in search of nectar, and return to the clean hive with their sacs filled with nectar fresh from the flowers with all their healing influences; and if a stray bee happens to get into the wrong hive she carries no infection.

This method not only precludes the necessity of handling frames to any extent, but it also precludes the necessity of compelling the bees to build new combs right from the stump, as it is safe to use full sheets of foundation or clean healthy combs, which insure a crop of honey if we tier up the hives to be treated so as to get a strong force of bees in the clean hive. This is the method practiced with sectional hives. I ask you, Mr. Editor, which is the more scientific as well as economical method. No, economy of labor is not to be found in the handling of frames under *any* circumstances.

I call your attention to this matter partly because I feel sure you did not take the time to give the matter due consideration, and partly because your error might influence some bee-keeper who contemplates adopting this excellent hive to reject the most scientific method of treating foul brood, as well as the one hive above all others in which economical manipulation is carried to perfection.

Birmingham, Ohio.

[The editor considers himself by no means infallible; and when a correspondent thinks that any of our editorial utterances are misleading we hope he will be free to come back and say so; and he can have all the space he wishes for his reply. When an able correspondent like Mr. Hand says he seldom finds any thing to criticise in our editorials we feel complimented indeed. Perhaps not all our readers will agree with him.

Referring to the editorial in our issue for June 1, page 389 last year, perhaps the reader will understand Mr. Hand's point of view better if we introduce right here the sentence or sentences to which exception is taken. Here they are:

If, on the other hand, one has had considerable experience in keeping bees, and wishes to manage a se-

ries of outyards for the production of either comb or extracted honey, with a minimum of labor, he possibly would do well to adopt the divisible-brood-chamber hive. It is true it would cost some more for the same comb surface, yet in the hands of the skilled bee-keeper it will produce some excellent results. But if foul or black brood, or any other brood disease, happens to be in the locality we would never think of adopting such a hive; for if one is likely to get one of these diseases in his apiary, the divisible-brood chamber proposition would be a fright, for it is not one that will permit of the handling of all its frames with economy of labor.

We will explain by saying that we had in mind not so much the trouble of *treating* a colony that had foul brood as being able to *locate* the disease in the first place in any particular hive at its very incipency. We do not know how this can be accomplished if foul brood is *known* to be in a yard (that is, has broken out in some hives) without going over *every inch of comb surface* in every hive at least once in ten days. Years ago, when we had foul brood in our home yard, we found it necessary to keep one man employed under a wire cloth cage examining brood. Whenever he found any bad cells he removed the comb, for our plan was to catch the disease at its very start, to prevent contamination of other hives near by. We do not know of any way by which the actual presence of foul brood in a divisible brood-chamber hive can be definitely determined except by examining every comb. Ordinarily speaking there will be twice as many combs in such a hive to look over and handle as there would be in a hive of ordinary standard dimensions of full-depth frames.

As to the Baldrige method of treatment, this has the merit of saving all the brood that is good, and leaving the work of melting up the combs at some convenient time, when the apiarist can take care of them to the best advantage. It would not, in our judgment, however, be a wise procedure for a beginner or an unskilled person. For that reason we believe that the ordinary McEvoy treatment is better, because the source of the infection is immediately removed. When there is fresh honey in the combs they should not be shaken but brushed. At this point our correspondent would probably take issue with us by saying that brushing and shaking increase the probability of infection; and that it would be better to follow the Baldrige treatment that does not involve any brushing or shaking. Right here there is a chance for an honest difference of opinion.—Ed.]

## A HISTORY OF THE BASSWOODS.

American, European, and Other Species.

BY J. E. CRANE.

On p. 442, July, last year, is a letter from W. J. Green calling attention to the difference in time of bloom in the European and American basswoods, followed by A. I. Root's reply. Having waited for nearly six months for some one to reply, and not seeing any thing on the subject, I "take my pen in hand" to see if I can throw any light

\* See GLEANINGS for Aug. 15, page 488.

AMERICAN BASSWOOD, OR LINDEN.

on the subject. As the linden is one of the greatest honey-producing plants in our northern States it is important to know all we can about this interesting family. The more is this true as the time has come when we must begin to raise timber to supply the ever-increasing demand for lumber; and basswood is one of the most rapid-growing

deciduous trees that produce good soft lumber.

There are recognized by botanists some twelve distinct species of basswood, or linden. Three of these are native to the United States, six to Europe and Western Asia, and three to Eastern Asia. Several of these species are known under a common name,

and other species of them under several names, and several running into varieties, so that the nomenclature has become very uncomfortably mixed, and we are not at all sure by the name given to what species it belongs. Nurserymen do not appear to be as particular as they should in giving the correct botanical name of plants they propagate.

Now let us see if we can bring order out of confusion. Let us first take our American lindens cut up into three species:

1. *Tilia Americana* (also known as *Tilia Caroliniana*, *American linden*, or *basswood*, which is too well known to need full description. It should be mentioned, however, that it is quite variable in its habit, size, shape of leaves, color of bark, and also time of bloom. Two varieties of this species are known as *Tilia macrophylla* a large-leaved variety, and *Tilia moltkei*, a very large-leaved strong-growing form that originated in cultivation in Europe. This species is found through the northern States from Maine to Minnesota.

2. *Tilia heterophylla* (also known as *Tilia alba*). This tree attains a height of 70 feet; has large leaves from five to eight inches long, smooth and shining above, whitish and tomentose beneath, with fruit globular, not ribbed; blossoms in July. Its home is in the Alleghenies and westward. This species has been sent out as *Tilia macrophylla*, thus confounding it with *Tilia Americana*.

3. *Tilia pubescens* (also known as *Tilia Americana*, var. *pubescens*), as it is similar to *Tilia Americana*; but it is a smaller tree with its winter buds, finely pubescent leaves smaller, obliquely truncate at the base; glabrous above, pubescent beneath; floral bract rounded at the base, fruit globose. This species is found from Long Island to Florida, and west to Texas. It is less ornamental than the other native species, and is rarely found in cultivation.

#### EUROPEAN SPECIES.

1. *Tilia petiolaris*, also known as *Tilia Americana*, var. *pendula*; in horticulture as *Tilia argentea*, var. *pendula* and *Tilia alba*, var. *pendula*; also as *Tilia pendula*.

#### SILVER LINDEN AND WEEPING LINDEN.

This is a medium-sized species with slender, somewhat pendent branches; leaves pale green above; silvery, and finely tomentose underneath; 3 to 5 inches long; petiole slender, as long as the blade; blooms in July; from eastern Europe; said to be one of the best of the European kinds.

2. *Tilia tomentosa*, also known as *Tilia argentea*, *Tilia alba*, *Tilia alba*, var. *Spectabilis*, also *Tilia alba pyramidalis*, white or silver linden, and is the larger white or silver linden of Europe, growing some 40 feet high, having a rather dense pyramidal head, leaves suborbicular, 3 to 5 inches across, unequally cordate, serrate, densely white tomentose beneath, with blade from 2 to 4 times as long as petiole; fruit slightly ribbed and tomentose. Time of bloom very variable. This species is from eastern Europe, is quite dis-

ting, and is known as the white lime of Europe, and is doubtless the same kind mentioned by A. I. Root on page 442.

3. *Tilia platyphyllus*, sometimes known as *Tilia grandifolia*. This is the broad-leaved linden of European plantations, and supposed to be the largest, reaching 90 feet in height. Leaves are large, green, pubescent often on the upper side to some extent, unequally cordate, petioles and veins hairy; fruit 5 rarely 4 angled, tomentose, and thick-shelled. This species is often sold in this country as *Tilia Europæa*. This species is very variable, producing several well defined varieties—*rubra*, with bark of branches very red; *pyramidalis*, an upright grower with reddish shoots; *urea* or *sulphurea*, with yellow bark or branches; *laciniata* or *laciniata rubra* with deeply cut leaves and reddish young bark; also *vitifolia*, vine-leaved.

To us the most interesting thing about this species is that it blossoms some two or three weeks before our American species, and is the earliest to blossom of any species of linden so far as I am able to learn.

4. *Tilia vulgaris*, also known as *Tilia Europea*. This species grows nearly as large as *Tilia platyphyllus*; has large unequal or oblique cordate leaves; smooth and green on both sides; tufts of hairs in axils of veins whitish; fruit globose or oval, tomentose; shell thick, and blossoms a week or ten days before our *Tilia Americana*. This is said to be the celebrated species of Berlin, and is often sold in this country as *Tilia Europea*.

5. *Tilia ulmifolia*, also known as *Tilia cordate*, *Tilia parvifolia*, *Tilia Sibirica*, *Tilia Europea*, and *Tilia microphylla*. It is of slower growth, and usually a smaller tree than *Tilia platyphyllus*; leaves small, thin, cordate, green above, silvery beneath, with tufts of rusty hairs in the axils of the veins; fruit globose, sometimes slightly ribbed, and very thin shelled. It is of special interest to us from the fact that it is very late in flowering—probably ten days or two weeks later than our American species.

6. *Tilia dasystyla*, or *Crimean linden*, is described as leaves tough and leathery, dark glassy green above, pale beneath, with tufts of brown hairs in the axils of the principal veins; bark of young branches bright green; leaves often obliquely truncate at the base; native of Eastern Europe and Western Asia.

#### ASIATIC SPECIES.

1. *Tilia Mongolica* is described as a slender tree with very small orbicular or ovate leaves, truncate at the base, usually three-lobed, cuspidate, coarsely serrate, with acuminate teeth, glaucous beneath, or green, on vigorous shoots; lyme rather dense, with stalk naked at the base—native of Eastern Asia.

2. *Tilia Mandshuria*—a tree attaining 50 feet, with spreading (often somewhat pendulous) branches, leaves large, from 5 to 8 inches long; orbicular to broadly ovate; cordate or truncate at the base; rather coarsely serrate with spreading teeth, floral bract almost adnate nearly to the base of the peduncle; fruit globose, thick-shelled; five furrows

with a slight cavity at the insertion of the pedicel. A variety has leaves edged with yellow or a lighter green, from Eastern Asia.

3. *Tilia Niqeliona*—a native of Japan, attaining a height of 100 feet with usually an oblong head; leaves ovate, truncate, or slightly cordate at the base, gradually acuminate, rather coarsely serrate, with incurved teeth 4 to 6 inches long; floral bract adnate almost to the base of the peduncle; fruit globose, thick shelled, five-ribbed only at the base; time of bloom not given.

Now, what of all this, or of what value to the bee-keeper? Let us see. We find that our *Tilia Americana* varies in the time of its bloom—I think fully ten days, for I find trees near together, one commencing to bloom many days before the other. If the weather is not too hot a tree will continue, after commencing to bloom, for two weeks, thus giving us about three weeks of bloom. It is probable that trees in forests or on high hills will lengthen the season. If we can find some other species that will bloom a week or ten days later, as Mr. Green and A. I. Root have told us on p. 442, we may add ten days to the length of the season. And, again, if we have or can find some species that will bloom ten days earlier than our American species we are doubling the season of bloom. I have shown in the above account of European species that there are at least two that are earlier by far than our American species. But isn't there some mistake about that? Can it be that Europe can furnish species that will bloom so much earlier and later than our own? It certainly is so, for we have a European species on our college grounds right here in this town that blooms from ten to twenty days earlier than our native basswood, as I have watched it for the past thirty years or more.

There have undoubtedly been large numbers of European linden set out in and near our large cities; and will not near by beekeepers watch the difference in the time of bloom, if any are observed blooming either earlier or later than native trees, and report, sending specimens of leaves and blossoms and fruit to State experiment stations for correct botanical name?

This is a work our experiment stations should take up, and find out the most desirable species to plant for timber as well as for the bee-keeper, that those who plant trees may do so wisely and to the largest economic value of the country. Can not our bee-keeping friends across the great water tell us more of the time of bloom, and value of the European species?

Middlebury, Vt.

#### CELLAR AND OUTDOOR WINTERING.

**A High Temperature Now will Mean that Brood-rearing will Start too Soon.**

BY J. E. HAND.

Packed in one end of our house cellar, four and five deep, are 105 colonies which were put in Dec. 5. In the center of the end

occupied by the bees is a window 14×28, opening underneath another building, the foundation walls of which are well ventilated. Said window has not been closed since the bees were put in. The temperature has ranged between 45 and 50°, mostly the latter. The cellar is apparently as dry as an upper room; and, notwithstanding it is entered every day, and sometimes oftener, the bees are very quiet indeed, and, to all appearances, are wintering perfectly. The hives are pushed forward on the bottom-board so as to give two openings at the bottom, and the tops are covered with a piece of carpet or heavy cloth. The high temperature will undoubtedly induce early breeding, which is not desirable, and from now on we will reduce the temperature by leaving the out-side door open every night, when the temperature is below freezing. We find that a high temperature and a dry cellar with a pure sweet atmosphere is a safe place in which to winter bees.

We always winter our strongest colonies out of doors, believing that a bee-keeper who would do credit to his chosen profession should be able to winter his bees successfully either way as well as to produce either comb or extracted honey at a profit.

Our outdoor colonies are for the most part in winter cases surrounded by two inches of sawdust on the sides and five inches on top. Some have sealed covers, and all have three thicknesses of carpet or heavy cloth, either laid upon a honey-board or upon the sealed cover, hanging down over the side of the hive, after which the sawdust is poured in and worked down around the hive, and the five-inch tray rounded up full. When a seven-inch waterproof cap telescopes over the winter case, the entrance is  $\frac{3}{4}$ ×3 inches.

Our bees are, for the most part, in sectional hives; and past experience has taught us that we have little cause for anxiety for their welfare.

We have been equally successful with the following method of outdoor wintering: Lay several thicknesses of old carpet or burlap sacks upon the hives, letting them come down well over the sides. Over this lay several thicknesses of newspaper, and over the whole push down an 11 inch waterproof telescope cap. For the latitude of Northern Ohio, all three of these methods seem to be equally successful; however, the latter one appeals to us on account of its simplicity of equipment and economy of manipulation.

A word about the much-mooted question of moisture-soaked absorbents. I don't know what causes it at Medina, but I do know we don't have it up here in the lake regions, notwithstanding the moist atmosphere. I suspect three thicknesses of carpet has something to do with it.

Birmingham, Ohio.

[We have no moisture in the absorbents over a sealed cover; i. e., a super cover sealed down with propolis so that no dampness can escape into the packing above. From your general description it would appear that you are using sealed covers, or

what practically amounts to that. Your sawdust packing, when pressed down *tight*, in effect shuts off all upward escape of warm air, and, of course, no moisture can escape. If the packing were loose and porous like chaff, moisture would rise and lodge in the packing.—ED.]

### EXTRACTING ALL THE HONEY FROM OUTYARDS AT ONE PLACE.

#### Hauling Extracting-supers in a Covered Wagon.

BY V. V. DEXTER.

We need all the information about black brood that we can get out here in Washington. One of our largest bee-keepers has either pickled or black brood all through his apiaries. I have read of no one using the same methods in extracting that I do; and possibly by telling my ways some one may gain new ideas. I live in town, and have about 500 colonies in 7 apiaries, placed all the way from 4 to 15 miles from home, and have about two extracting-supers, Langstroth depth, for each hive.

I do my extracting at home, hauling the honey there in a canvas covered spring wagon painted white. It is bee-tight, and has a small screened window with bee escapes on each side. The door is in the back end. The wagon will carry about 2000 lbs., or 50 supers; but this is hardly enough, and some day I am going to have a larger wagon, provided foul brood does not get the better of me.

My extracting-house is 20 feet square, and has a cement floor. Across one end is a platform about 8 feet wide, one end of which is partitioned off for a warming room, the floor having openings in it to admit heat from a stove underneath. On the end of the platform opposite the warming-room is the extractor, and next season I expect to have an engine near the extractor; but down on the cement floor stands a 2000-lb. tank into which the honey runs from the extractor. After the specks of comb have risen to the surface the honey is run into cans which are placed in a hole in the floor under the faucet.

There is a door opening outdoors from the platform, through which the full combs are unloaded and carried into the warming-room. The threshold of the door is on a level with the platform, and also about on a level with the floor of the wagon-box, which makes unloading more convenient.

This year I melted my cappings as they fell from the capping knife; but I do not like that way, as it is very uncomfortable working over a hot stove on a warm day, and we do have some very warm ones here. Next year I shall uncap into a large dishpan and then empty the cappings into the capping-melter in another part of the room. I would leave them to be melted later, but it is not nice to have a lot of cappings lying around.

The past year has been practically a failure here so far as bees are concerned. The

farmers are plowing up the alfalfa, our principal honey-plant, and putting in fruit, from which the bees gather almost no honey, as our springs are usually cold and windy.

North Yakima, Wash., Jan. 15.

[A number are finding it more convenient to uncap into a separate can, which may be emptied, as often as full, into the melter. Others confine the heat of the melter by wrapping several layers of asbestos paper around it so that the heat radiated is not objectionable.—ED.]

---

### MORE ABOUT COTTON AS A HONEY- PLANT.

BY J. D. YANCEY.

As to the quality of cotton honey, I can say from my own experience that it varies in color from light amber to almost water-white. While I do not consider it the equal of white-clover honey in flavor, it is superior to basswood. My experience with it dates back some 14 years to Hunt Co., Northern Texas, where it was our main dependence for a honey crop. The bees worked upon it continuously, more or less (depending on whether the weather was favorable to the secretion of nectar) from early in the blooming season until long after the first frosts. As mentioned by D. P. Hunt, page 21, Jan 1, the flow increases toward the last of the season; and if we can get two weeks of nice weather after the first frosts it generally amounts to a considerable increase in our crop.

I distinctly remember a season when we secured a considerable extracting after we had given up all hopes of a crop, and the bees went a distance of three to four miles to the river bottoms, where the cotton had not been injured by the severely dry weather as it had on the prairies around us. The honey, however, from cotton growing on heavy bottom land is not so light-colored nor as finely flavored as that gathered on the lighter and dryer soils of the uplands—at least such has been my experience.

Besides the nectar-glands mentioned by Mr. Hunt, there is on the under side of the leaf, on the center rib, a small gland that at times secretes a considerable amount of nectar. This gland seems to be the most active about the time the leaf reaches full maturity. When atmospheric conditions are just right, such large drops of nectar will collect on these leaf-glands that one may readily taste it; and a bee has to visit only a very few to obtain a load. At such times they neglect the blossoms entirely, and the honey comes in with a considerable rush. I could not tell that this honey was any different in either color or flavor from that gathered from the blossoms.

In a ten-year residence in Southern Texas I have never noticed bees work on cotton as they did in the northern part of the State.

Bridgeport, Wash.

## HEADS OF GRAIN FROM DIFFERENT FIELDS

### FLORIDA HONEY THAT FOAMS WHEN PUT IN A WARM ROOM.

What can be done with honey that becomes foamy or braded like when placed in a warm atmosphere? What I have in mind is honey from tupelo and snow-vine. My theory of the cause of this is that the acid from each is such that it will not do to put the two together; and the only remedy I know of is the mixing of a proper proportion of orange honey.

Washington, Pa., Dec. 20.

H. E. DILLE.

[As the questions here asked refer to Florida honeys that foam they were referred to Mr. O. O. Poppleton, who is an acknowledged authority on Florida honey and Florida bee-keeping. His reply will be read with interest.—ED.]

*Mr. Root:*—Yours of Jan. 22, inclosing a letter from Mr. Dille, has only just reached me, owing to my being on an inspection trip to my bees down on Key Largo, away from mail communication.

I have had only a limited experience with foamy honey, and most of that was unsatisfactory. I had half a barrel of such honey in Iowa, and that cured itself by being allowed to candy solid. I then skimmed off the liquid honey that remained on top of that which was candied, and all the rest. The portion which had candied very hard and solid was first class. It appeared as though the thin foamy part of the honey would not candy. The poor part of the honey, that which remained liquid, was only a small part of the whole—less than a twentieth. If this particular lot of honey Mr. Dille refers to is in the North, where it will candy solid, I would suggest that he try allowing it to do so in a suitably shaped vessel that will allow it to be properly skimmed after being candied solid except the top; then by the usual process reduce the candied part of the honey to its original liquid condition. It is a question with me whether, in this particular instance I refer to, the real curative agent was the candying or the after-reliquefying by heat; but I suspect it needed both.

Honey kept in a southern climate does not candy solid enough to use the above process, and I have had only the one experience referred to in the North; and all bee-keepers know how apt single experiences are to lead one to wrong conclusions; so what I have written is only a suggestion which may call out something much more valuable.

In addition to the above I would say that I do not think Mr. Dille's theory of the cause of the foaming is correct. Mixing two kinds of honey would cause no trouble unless one of them was of bad quality. I have seen some honey that was full of air-bubbles under the caps, and such honey is sure to foam after extracting. It seems almost impossible for the bees to cure some kinds of honey properly, but they will seal it up all the same.

Stuart, Fla., Feb. 5.

O. O. POPPLETON.

### A NEW WAY OF USING THE CAPPING-MELTER.

I have used a capping-melter the past season, and I think it is one of the best things that have been put out of late. I injured the honey the first time by having too much heat; but afterward I used just enough heat so that the wax would not cool in the end of the spout and clog, and the honey so obtained is improved. I let the cappings fall from the knife into a tub and drain a short time, and then dip them into the melter as needed. The cappings are all melted by the time the honey can be drawn from the extractor. I have two reasons for allowing the cappings to drain before putting them in the melter. I have two uncappers part of the time, and the capping-melter is hardly big enough for both of them. A large galvanized tub with a quarter-inch-mesh strainer allows two-thirds of the honey to drain out in a few minutes so that there is not so much to heat, and quicker work can be done. Then I turn the heat down so that the wax will cool and harden in the outer end of the spout, then increase it slowly until it runs freely. By this process no harm is done to the honey.

Vesper, Wis.

A. B. WHITE.

### TWENTY YEARS' EXPERIENCE SHOWS THAT BEE-STINGS DO NOT CURE RHEUMATISM.

Dr. A. F. Bonney, p. 784, Dec. 15, is right in his opinion of bee-stings as a cure for rheumatism. Those having old volumes of GLEANINGS will, by referring

to p. 994, Dec. 15, 1889, see that I was enthusiastic in an article hailing the bee-sting remedy. Now, after twenty years of experience with rheumatic pains and bee-stings as a side-issue, I have come to the same conclusions as has Dr. Bonney. Take one hundred persons who have had rheumatism and been cured, you will find that scarcely any two of them used the same remedy. The fact is, very few of them ever experienced rheumatism to the degree that I have and are now cured. Sometimes the terrible malady will apparently leave its victim; but in an old chronic case like my own there is no cure known or guaranteed except through quackdom.

### THE MILLER CAGE DESCRIBED YEARS AGO.

IN GLEANINGS, p. 769, Oct. 1, 1889, there is a cut of a cage that I devised to introduce laying queens on the candy plan, and an article describing my method of using it. The Miller introducing-cage now used almost universally is identical with my device in every detail, except that the Miller cage is flattened and will go between the brood-combs without spreading them, and the queen is released without further molestation, which is an important factor in introducing queens successfully.

Shickshinny, Pa.

S. W. TAYLOR.

### ARE EXCLUDERS HONEY-EXCLUDERS?

In my opinion excluders are honey-excluders to a certain extent. The excluder is a tight fit for a honey-laden bee. Just take it home to yourselves—if you had a pack on your back, and had two doors you could go through, wouldn't you choose the larger one? If the flow is light I can imagine them saying, "Oh, well! I don't want to get any honey to-day. There isn't much honey, anyway, and I hurt myself so much pushing and shoving through those bars." To prove this, I will say that the bees do not carry honey below half so much when the excluder is on, and I presume it is for the same reason that they do not carry it above quite so willingly as though the excluder were off. The hive that has an excluder on always has more honey in the brood-chamber, and less brood than the one that hasn't one. And then they say the excluder queen was not so prolific as the other. Strange that it should be this way 80 times out of 100 at least.

As to distance making a difference in the amount of honey gathered (see page 22), I should say it does. When the distance is close they make more trips during the day, and it stands to reason that if they have to go a mile they can't gather honey as fast as if they had to go only a yard. As well ask, does a high wind have a bearing on the amount of honey gathered? Are they not both a hindrance? Their water also should be close at hand so that they won't have to waste more time than is absolutely necessary.

MRS. M. E. FRUIT.

Ranch Vigo, Eola, Tex., Jan. 7.

[There has been some discussion on this question, pro and con; but some of our best bee-keepers—those who produce honey by the carload—make the unqualified assertion that excluders do not in any way interfere with the amount of honey stored above. While they do exclude pollen to some extent, this very exclusion is something that is desired, for it is better to keep pollen out of the surplus honey.—ED.]

### HOW FAR DO BEES FLY?

Myself and neighbor own the only Italian bees in the county, and it is seven miles in an air line to Hamburg. Last spring I transferred eight colonies for Mr. C. L. Baker, of that place. I commenced about 9 o'clock, and by 10 o'clock I noticed 5 or 6 Italians there attempting to rob. By 3 P.M. it looked as if I could have hived a pretty good swarm of them. The next day there were more of them. Now, where did they come from?

Hamburg, Ark., Dec. 16.

W. D. JOHNSON.

[It is our opinion that your own Italians did not fly seven miles. While we have known bees to go that distance over a body of water, it is very doubtful whether they would go as far as that unless it were over a valley from one hill to another; and even then the maximum distance, we should say, would be five miles. The reports that have come in during the past few months have indicated pretty conclusively that, as a rule, bees do not fly over an average range of much more than a mile and a half; and apparently most of the honey is gathered within a radius of one mile from the yard. While there are exceptions, of course, yet these exceptions only prove the rule. If you will look a little carefully and make some inquiry you will find, in all probability, that there are some Italian bees in the locality not far from where you did the transfer-

ring. If you had taken pains to "line them up" we think you would have found they were not going to a place seven miles away, but to some point near at hand.—ED.]

**WHAT IS THE YELLOW DUST UNDER THE BROOD-COMBS?  
THE PROPER SPACE UNDER THE BOTTOM-BARS  
IN WINTER.**

1. What is the yellow dust to be seen on the bottom-board of the hive during the winter months—sometimes considerable? I have seen something like it during the summer when bees gnaw combs. Are colonies in good condition when considerable of that dust appears?

2. Will the bees clean up dusty sections that have starters in them? The reason I ask this is because at times this is a dusty country, and otherwise I could not save any sections by the superfluous t over from a previous year and which have been drawn out considerably at times.

3. For colonies wintered outdoors, is it advisable to have much space below the frames and above the bottom-board during the winter, considering them to have, of course, the entrance contracted to  $\frac{3}{8}$  x 6? Chadron, Neb., Feb. 1. LEE CARD.

[1. We do not know that we are able to give a really positive answer to this question. The yellow dust may be particles of propolis, or the leavings of pollen which the bees do not use, or a sort of pollen mold or dirt. Any dust or litter that comes in contact with bees will generally become more or less soiled, and take on a yellow color. The suggestion has been made that bees use only the pollen that has been mixed with honey. If the combs are well supplied, the presumption is that all the pollen in the form of dust that brushes off from bees that come into the hive is neglected or not used. If so, it may be and probably is taken at other times when there is a scarcity of nitrogenous food in the hive.

Yellow dust on the bottom-board of hives that accumulates during the winter months is no different from that which accumulates at other times of the year, probably. In any event, its presence does not signify that there is any thing wrong with a colony. There will nearly always be such leavings with any good strong stock.

2. A good rousing swarm, when it enters its new quarters, will do a good job of housecleaning; but if dusty sections be placed on a hive during a big honey-flow the probabilities are that the bees would not stop to clean them up. They might do so if they had plenty of time. It would, therefore, be advisable to have all sections as clean as possible.

3. In either indoor or outdoor wintering it is advisable to have as much space under the frames as possible for the accumulation of dead bees. Their carcasses will often close up the space between the bottom of the frames and the bottom-board; and during the latter part of winter and early spring the accumulation will very often clog up the entrance. A closed entrance usually means death to the colony. The greater the space between the bottoms of the frames and the bottom-board, the less liability of clogging the passage-way to the entrance. Generally it is not practicable to have a deeper space under the frames than  $\frac{3}{8}$  inch in the average hive. The modern hives turned out by most manufacturers now have reversible bottom-boards having a  $\frac{1}{2}$  space on one side and  $\frac{3}{8}$  on the other. With such boards one can give additional space. The entrance should, of course, be  $\frac{3}{8}$  x 6 inches, or preferably  $\frac{1}{2}$  x 6 or 8 inches; but with such a narrow slot it is very important to see that the dead bees are raked out occasionally, especially toward spring.—ED.]

**WHY DID THE BEES UNCAP THE HONEY?**

I don't understand my bees this fall. They seem to have uncapped a quantity of honey. Not long ago they seemed to have enough for the winter all capped, but when I looked at them a fortnight or so after, they had uncapped nearly all of it. There seemed to be a good deal of honey; but very little of it was capped.

MISS MARGARET V. HAMILTON.

Aurora, Ind., Dec. 17.

[We are unable to explain why your bees should, within a period of a few days, uncap nearly all their honey. The only suggestion that we can offer is that robbers from without made an onslaught on this hive; but if that had occurred, you or your neighbors would have had knowledge of it, and the robbed colony would have been deprived of all its stores.

Can any of our readers offer any satisfactory explanation?—ED.]

**WHAT IS THE LEAF-CUTTER BEE?**

Will you please tell me what the leaf-cutter bee is? I have never observed it.

Bradshaw, Neb.

C. B. PALMER.

[This was referred to Prof. H. A. Surface, who says:]

The editor has forwarded me the letter and specimens. I find upon examination that these are the nests of the leaf-cutter bee, belonging to the genus *Megachila*. The larvæ, or young, are contained therein. This bee makes its nest by cutting round pieces out of leaves and pasting them together, as you have observed. Such are the facts in the case. As to how this comes to be so, there is some speculation and the rest is guesswork. However, it is my idea that the parent leaf-cutter made her nest inside the bee-hive, and the honey-bees left this without notice for a while, perhaps because they were very busy with the nectar-flow; but when they realized the presence of an intruder they cast it out and you found it in the entrance. There may be some other explanation for its presence there, and I suppose that another person's guess might be as good as mine in this regard.

H. A. SURFACE,  
Economic Zoologist.

Harrisburg, Pa., Sept. 22.

**FEEDING ARTIFICIAL POLLEN INSIDE THE HIVE.**

I have been reading the article by F. Dundas Todd, p. 53, Jan. 15, and will offer my plan of feeding pollen. I take a piece of canvas (8 or 10 oz. duck), one inch short of length and depth of frame used in the hive. I tack a  $\frac{3}{8}$  strip on each side of the top edge to act as a top-bar, so that the canvas may hang on the rabbets like a frame. Then I paint each side of the canvas with hot extracted honey and hang it in a very warm place until the cloth appears quite gummy. Finally I coat a large plate very thinly with honey, spread on the flour, and mix well. Care should be taken not to have it sticky. I find a putty-knife is a fine thing with which to mix it, then spread the mixture on each side of the canvas. One of these frames hung in a pollen-famine colony will help wonderfully.

Three Rivers, Mich.

WM. Z. RUGGLES.

**DYSENTERY STAINS WITHIN THE HIVES.**

Did you ever know your bees to smear their hives all over inside of the hives? I have two that did today, and yet they did not fly much. What would you do with them? Those I fed on sugar are all as nice and bright as they were in the fall. The two in question have all honey-dew.

ROBERT INGRAM.

Sycamore, Pa., Jan. 20.

[When a colony has dysentery so badly that it stains the inside of the hive it is usually past recovery unless settled warm weather comes on almost immediately. We are not surprised that there should be so great a difference in the condition of colonies fed on sugar syrup and those having only honey-dew. Reports have shown this before.—ED.]

**GETTING RID OF RATS WITH SULPHUR.**

I moved to my present home two years ago, and found the place alive with rats. They were in the barn, house, out-houses, woodpile—in fact, everywhere that a rat could hide. Last year in putting up my corn I sprinkled sulphur in it as I put it in the crib; also on hay, oats, etc., and now there is not a rat on my place. Some of my neighbors have tied sulphur, and they have no rats. I use about one pound of sulphur to 100 bushels of corn. I sprinkled it around well next to the wall. I believe that rats can be driven entirely away by the use of sulphur.

Brookston, Texas.

J. R. SCOTT.

[Has any one else had any experience in the use of sulphur in getting rid of rats as here described?—ED.]

**HONEY THE SAME PRICE TWENTY YEARS AGO.**

It is rather poor encouragement for bee-keepers when honey is 12 to 16 cts. a pound, just as it was 23 years ago. All other things are double in price.

Williamsville, N. Y.

WILLIAM IRR.

[See article by O. L. Hershiser, on page 104, Feb. 15th issue, for a general discussion of this question.—ED.]

**FOUL BROOD IN A BEE-TREE.**

I cut a bee-tree this fall that was two miles from any bees in hives. It had foul brood. So you see bees can have foul brood in trees as well as in hives.

Shelton, Conn., Nov. 29.

EUGENE S. HUBBELL.

[This is the first report we have received of this character.—ED.]

## OUR HOMES

By A. I. Root.

Of such is the kingdom of heaven.—MATT. 19:14.

Some years ago when *potatoes* (instead of "chickens") was my hobby I got a letter from a man in Northern Michigan who was not only a potato-grower but a great genius for *growing* almost every thing; and just then he was preparing to start melons in strawberry-boxes under glass, to be planted in the open ground later. I found out he was, by accident as it seemed, within about a mile of some land up there that I had owned for some years. Further correspondence resulted in a visit to the home of James Hilbert, of Bingham, Lelanau Co., Mich. I can't tell you now of the many things we had to look at and talk over; but along toward dinner-time Mrs. Hilbert said to one of the little girls, "Alice, could you dig some potatoes for dinner?" and as I took a look at the shy, slender little daughter of hardly a dozen years, I ventured:

"Alice, can't I go along and help?"

Her reply was hardly audible; but she gave me such a shy, sweet, childish smile I *knew* she was pleased, even if she did not say so. Then and there commenced one of the pleasantest friendships of my life. The potatoes were out near the barn where friend H. had been doing some "high-pressure" gardening, and I almost went wild with enthusiasm when Alice skillfully threw out twenty or more nice potatoes from a *single hill*. When her mother thought such a child could dig potatoes for dinner I was surprised, and it would have been a task on our average Ohio soil; but in that heavily manured, soft sandy soil, with a light shiny *potato-hook*, it was no task at all, even for a little girl. Alice was not only skillful, but she could tell *me* (who had published a *potato-book*) a lot about potato-growing in that region.

After Alice and I had become so well acquainted that she could talk to me freely, I found she had been reading my Home papers long before she ever saw me. There was a simple, honest frankness and innocence in her make-up that I think I had never seen before or since. Once on our way to Sunday-school she said, "Mr. Root, I loved you before I ever saw you." About that time, or later, she said also, "Mr. Root, I want to be a Christian, and I want you to be my teacher, and to show me how." Was not that a sacred and solemn responsibility placed on my weak shoulders? I told her I would gladly help all I could, and she used to tell me of her troubles in school, and ask me if she did right in her way of settling them, etc. Her father gave me an illustration of her loving and forgiving disposition. He said that, from a child up, when he felt obliged to punish her for some little thing she would come to him before the tears were dried on her little cheeks and say, "Papa, I love you." She evidently wished to have him understand that her faith and confidence in him were so

great she felt sure he would never correct her unless she deserved it, and that it was for her greatest good. Can we of mature age show this confidence and trust in our heavenly Father when we are chastised?

If I am correctly informed, Alice was baptized and taken into that Bingham church amid the hills, alone by herself; and *before* the revival I told you about some years ago. I think she told me also on one communion day that she, the mere child, was the only one in the whole audience who would partake. I presume the older Christians, from some mistaken notion, considered themselves "too unworthy."

Dear friends, my heart is full of sadness and sorrow to-day, for our yesterday's mail informed us that my gentle friend Alice is dead, and buried in that Bingham cemetery on the snow-capped hill near that little church. She wrote us last summer that the doctors told her she had an incurable disease, and that her stay in the world was not to be long. She said the Savior I taught her to trust in and love was ready to receive her, and she was ready to go, but that she disliked to leave her *two* motherless little girls. I wrote back to her to cheer up; that I would be up there soon, and may be we could persuade her to stay with her husband and the two little girls in spite of the prediction of the doctors. I wrote her something like this:

*Dear Friend Alice:*—You have paid me a great compliment by saying I have taught you how to *die*. Now, God grant it may yet be my privilege to teach you how to *live*.

I had in mind Terry's teachings, etc. Well, I fully expected to go up to that "old cabin in the woods" last fall, but I didn't get around to it. I fear that Simplicity incubator had something to do with it. May God forgive *me* for letting *anything* stand in the way of my duty toward my old friend Alice.

Kind, gentle, loving Alice is gone, and we can not call her back; but her brief bright life should teach us some lessons and point out some warnings.

Mr. Hilbert is a great worker, or was one. His children, like himself, have all been great workers. I have told you in years past how many potatoes they dug and picked up in a day. With his wonderful crops of strawberries, cherries, peaches, etc, his whole family *had* to work. I feel sure Alice worked too hard when she was young and growing rapidly. I often protested; but she was ambitious, and had the Hilbert enthusiasm. I am sure my good friends Mr. and Mrs. Hilbert will ex-use me if I speak of another thing. It *used* to be quite the fashion then to have many parties that kept the young people out late. Before Alice came into the church she was out nights altogether too much for one of her age. Her father "scolded," but the young ones were headstrong.

Once when I was there he was up bright and early, and was going to hustle up all the youngsters. I plead for more time for them to get their sleep, reminding him they were

late getting home. He declared the best way to punish them for disobeying his positive command was to *make* them get up at the usual time. He may have been right; but let me beg of you, dear fathers and mothers, beware how you choose any method of discipline that breaks the needed rest of these young ones God has placed in your care.

Last, but not least, Alice, with her wonderfully loving disposition, was married and became a mother several years too soon. If I in my advice about marriage have induced any boy or girl to get married while in the "teens," I want to take it back. No man or woman should think of assuming the sacred and solemn obligations pertaining to married life until such person has arrived at *full maturity*.

Almost the last time I saw Alice she came over to our "cabin in the woods" when Mrs. Root and I were getting ready to leave for Ohio. I was burying some choice potatoes that I wanted to plant up there the next spring. Alice had grown taller, and thickened up, until she was quite a strong healthy-looking girl of perhaps 16 or 17. I pronounced my potato-pit ready for winter. She took exceptions to my work.

"Mr. Root, your potatoes will all freeze if you leave them that way. I am 'an old experienced hand' in such matters. Give me that spade."

I attempted to remonstrate, but she laughingly declared she would take the spade away from me unless I handed it over. I shall always remember with what grace and skill she made a neat-looking potato-pit. I remember wondering at the time if some young man had not already gotten his eye on her. She was then "fetching up," as it were, after the hard work of childhood, and was just about to "bud and blossom" into glorious womanhood; and it was just about this time, or a little later, that she married. Ask Terry; ask the doctors and our great humanitarians what *they* think about marriage at such an age. At barely 20, when she ought to have been a blessing to the world, she was laid under the wintry sod, leaving two little motherless girls.

May God in his great mercy help us to learn the lessons he is striving to teach in this present age of progress, especially the lessons in regard to these frail bodies he has given many of us to care for.

---

*Gentlemen*.—Enclosed find check for \$2.00. Please send two copies of "How to Keep Well and Live Long," by T. B. Terry, to the addresses inclosed. I have enjoyed reading mine so much that I want two more copies for these friends.

Stroudsburg, Pa., Feb. 2.

W. H. TRUSLOW.

The above is one of the characteristic letters we are getting regarding Terry's book. Our first supply of these was exhausted in less than two weeks from the time the first notice appeared. We were obliged to keep some of our friends waiting a few days before the second lot was ready, but we have now another good stock on hand. In all our experience we have seldom found a book selling at \$1.00 or more that has been so favorably received as this book; and from no one have we had a single word of complaint regarding it.

## POULTRY DEPARTMENT

By A. I. Root.

---

### GETTING EGGS IN ZERO ° EATHER BY MEANS OF A LAMPLESS BROODER.

On page 62, Jan. 15, I mentioned the Clough lampless brooder, and said it would house half a dozen pullets until old enough to lay, etc. Below is an account of a recent experiment by the inventor:

*Mr. A. I. Root*.—It may be of great interest to you to know that we in the frozen North have been and are now having a most severe winter—snow or sleet most of the time; snow a foot or more deep; and with the rain, hail, and sleet it is more ice than snow. Railroads and street-cars are blocked half the time—coal very short. With me every thing is w. l. I am very busy, and at the same I am making some experiments this cold weather that I could not make if we had a mild winter.

Perhaps you have noticed that I have said something about keeping laying hens for eggs in my brooder, and said that a hen-house was not needed, etc. Well, on the 15th of last November I went to my neighbor's and bought eleven Buff Orpington hens. They were one year old, and were laying from three to five eggs per day. I took them home and placed them in my scratching-shed; and before the snow they had the run of the lawns. They did not stop laying because of their new surroundings, but they were not all in perfect health. Some of them had a slight cold, or roup, as it might be called; but as I claim my brooders are a good remedy for many chicken diseases it did not frighten me. I placed a brooder in the shed for them to roost in; but as they did not know any thing about "Clough's lampless" they commenced to *look up* for perches to roost on when night came. I expected this, and so was on hand and gently guided them into the brooder. It was a hot time for them, for it was warm weather, and so I let them nestle around outside the brooder, with two or three inside of it. This went along all right until Dec. 8, when the thermometer registered zero, and then the hens did not need any urging to enter the brooder, and they did not come out to cool off either. Some of them would stick their heads out for a few minutes, and then move back and let some others come near the door. Well, they produced the eggs just the same. That day they laid eight eggs. Since that time it has been 23 times from zero to 20 below, and these chickens (or hens, rather) have laid every day from two to seven eggs to date. They have become entirely well, and are in better condition every way than when I bought them. I have made inquiries all over this city, and outside to neighboring cities, asking the question, "Do you get any eggs this cold weather?" The answer has been, "No eggs."

I will now tell you how I fed them after the snow came, and they did not get out. Their first feed is hash in the morning, any time from eight o'clock till ten, just as I happen to feel about getting out this cold weather. This hash is made of the scraps from our table of four people, and sometimes it is not very abundant, because we eat up close. It consists of every bone and gristle from the meats; potato, onion, squash, and apple parings, not cooked, but all thrown into a pan together. To chop this into hash I made a special chopper with a hopper about one foot high and six inches in diameter. This hopper is on a solid block of wood. With a heavy chisel having a long handle to it I churn up and down in the hopper for only a few minutes, and every thing, bones and all, is made into the nicest chicken hash possible, and there is not a machine made that will work like this knife. Sometimes the hash will have too much water in it, and be too "mushy" for chicks. In that case I dump in a cup of bran and oats until it takes up the surplus water. For the last month I have put in a pint of alfalfa meal scalded, and this makes their droppings look as they do in the summer when they are getting what grass they want.

This hash is fed in round feed-pans set on legs about ten inches high; and it is a pleasant sight to look at them as they stand around that feed-pan. There is no musing, and, by the way, this feed-pan is the only

good way to feed chickens. The pan is made by using a ten-cent basin. Take four pieces of narrow board and punch a hole through the edge of the pan and drive a nail in, letting the legs flare out a little; then put a cross-piece from one leg to the other, and you will have a feed-pan that the chickens will not tip over nor muss in, and they can scratch all around and under it, and it really takes up no room. Well, hash is the morning meal. After this is all eaten, a pint of bran, oats, and wheat mixed is placed in this pan for them to eat at any time. When this is gone another is given, but not over two a day, making one quart. Along in the afternoon I give them two ears of corn scattered in the straw. I wish to say that I have beef-scrap on hand all the time, so when there is not much meat or bone in the table-scrap I put about a grill of beef-scrap into the hash-hopper. The water is heated in a coffee-pot and taken to them once or twice a day. Cold days it is boiling hot when taken out, and it will be three hours before it begins to freeze. The hens will not drink it until it gets to the right temperature, of course. They seem to use judgment in regard to this. When this water becomes cold, and ice is in it, another pot of hot water is poured in, when the ice soon disappears. At night the water-dish is emptied. This water-dish is made like the feed-dish, with the exception that four light pieces of wood are run up to a peak above the water so that the fowls can not hop up on the edge of this pan and get wet.

Now figure what it costs to feed these hens. I figure that the eggs they have laid cost less than one cent apiece, or that I am keeping these fowls at a cost of three cents a day, paying market price for every thing they eat except the table-scrap and the little time taken to care for them. You will notice that I have no feed-hoppers, so that the fowls can eat all the time. I do not think it the right way to feed. These eleven hens have laid eggs continually, I was told, since ten months ago, not stopping during the moulting season. The lady of whom I bought them told me she fed them about as I have, although she did not have the conveniences I have in the shape of tools, brooder, etc. She said they did not lay last winter, as they were then too young.

Now, Mr. Root, this way of feeding is a practical one, and is not forced. It is not a two-hundred-egg yield per hen, but it is a winter yield when no hens to speak of are laying. The number is 238 eggs from Nov. 15 to date—53 days, or a little better than four eggs a day.

Aurora, Ill., Jan. 13.

V. W. CLOUGH.

I believe it is pretty generally agreed that artificial heat for laying hens is not a success; but economizing the heat of the fowls, as above, is all right. It amounts to the same as giving horses and cattle good warm stables; and these fowls, it will be understood, can at any time put their heads out at the door and get cool fresh air. Perhaps I should explain that this brooder that accommodated the eleven laying hens is 2½ feet square, and perhaps a foot high inside, with "woolens" overhead to keep them warm.

The whole experiment as given above is really in line with the Philo system of keeping fowls *successfully* in a small space.

#### SPROUTED OATS OVER A FOOT LONG FOR CHICKENS.

Somewhere I think Edgar Briggs has said that chickens will eat oats when the oats have grown six inches high; but I could never get ours to swallow them when a good deal smaller, and I was uncharitable enough to think the statement an exaggeration; but, listen. Just before my brood of 70 (the ones the possums got into) were hatched, I cleared up a strip of woodland near their brooder, about 10×40 feet, and sowed it to oats so as to have them ready when the chicks were old enough to take them; and after the demise of the chicks the oats were left growing. As it was new land where one seldom gets much if any thing the first year, we cleaned out a

poultry house and worked in the whole contents on this strip. On this light sandy soil we have only to work under the roosts with hoe and rake every morning to have a nice sweet-smelling poultry-house all the time.

I think this house (of, say, 25 fowls) had been treated this way for six or eight weeks, when two wheelbarrow loads were put on that 10×40 strip. Well, for a week or two past, people have been stopping to inquire what grain or grass it was that gave such a beautiful rich dark green. I supposed it was altogether too tall to feed chickens, and was figuring on what I should do with it. Wesley gave some to the laying hens; but he said they didn't seem to want it. Finally I pulled up some from some very rich spots, and, shaking all the dirt off, carried it out to the "biddies." Now, these particular biddies have a sort of notion that I usually have some choice tidbit for them, and so they came up and began to examine and sample the luxuriant oats. I first pulled the rank stalks to pieces so they could swallow them, and by a little training I taught them the trick of swallowing oats not only a foot tall, but some actually 15 inches from tip of blade to the root. It is really comical to see them commence at the tallest blade or leaf and gobble it down until they come to the great bushy root, and then, after swallowing that too, and smacking their lips (or bills) to express the satisfaction it gives, they go for another. Since the fowls in that particular flock have learned the trick they will "get away with" a bucketful in a very short time; and my biggest egg-yield of the season followed right after this heavy feeding with green oats. Don't you see I have not only made *another* wonderful discovery, but I have made two of them? First, keep your chicken-coop clean and sweet all the time; and, secondly, use it as I have described in providing the most wholesome food for your fowls at even less than "15 cts. a bushel."

THE "BUTTERCUPS" UP TO DATE, FEB. 10.

The pullets are small, but quite handsome, though not laying yet. The cockerels, however, have manifested such evidences of precocity that I have placed three Leghorn hens in the Buttercup pen; and if we can't have full-blood Buttercups just yet we can have a few half-breeds just for the fun of it. I think the Buttercups are now about 4½ months old.

#### SOME OF OUR POULTRY LITERATURE FOR 1910.

In my hands is a book for which I have just paid \$1.00, entitled "The Kellerstrass Way of Raising Poultry." Just below the title on the cover we read:

You can read this book in 35 minutes; but it took me thirty-six years to write it. ERNEST KELLERSTRASS.

I suppose most of you know that Kellerstrass is the man who owns the \$10,000 pullet, and the poultry-journals are now telling us that he has sold during the past season 1024 eggs for \$2048—that is \$2.00 for each egg, or \$30.00 for a setting of 15 eggs. These eggs didn't come from "Peggy" either, but

from 30 of his best breeders, selected from a flock of 5000 or 6000. The book is a valuable one, even if it does contain less than 100 pages, and about 40 of these pages are taken up with testimonials from his customers who paid \$2.00 each for 15 eggs. The book is a big improvement in paper and print over the other dollar books that exploit "systems;" but why didn't Mr. K., with that big lot of money, put a cloth cover on his book and make it a little larger? In many respects the "book" is only an advertising medium for his \$2.00 eggs, such as our incubator people send out free of charge; and, to cap the climax, one of the pages in the back part is all taken up with the announcement that if you want his catalog of prices with *pictures* of the things described in the book (for which you have already paid a dollar), you must send *four cents* to pay the postage on the catalog. Evidently Mr. K. and some others (Burbank, for instance) do not expect to do much for the "dear people" unless they pay for it in good round dollars.

Now, I am glad to say Mr. Kellerstrass seems to have developed a wonderful strain of egg-laying White Orpingtons. The editor of *Reliable Poultry Journal* wrote to 84 people who purchased the \$2.00 eggs, and *seventy-two* replied. Mr. K. seems to have a fashion of making his customers satisfied (and well he can afford to), and a lot report getting 200 or more eggs in a year from pullets from the \$2.00 eggs; and I notice one report of 265 eggs in a year. The \$2.00 eggs are from 30 breeders selected from five or six thousand by careful trap nesting.

I want to call attention again this year to the Cyphers catalog. It contains a "secret" of more value, in my opinion, than any I have found in the "System" books—viz., a plan by which you can raise the very *best* chickens, and neither feed them nor clean out the litter oftener than *once in two weeks*. Our friends will remember I copied the process from their catalog about a year ago, and since then they have proved again the superiority of the method (deep litter feeding), not only for young chickens but for *taying pullets*.

## HEALTH NOTES

---

### MILK "STRIPPINGS" FOR CONSUMPTIVES.

Toward forty years ago, when I was taking the "beef diet" with Dr. Salisbury, he had a patient threatened with consumption, and by his orders this patient took about a pint of milk strippings right from the cow, night and morning. This patient is still alive and enjoying fair health, so far as I know, and the whole matter was brought to mind by the following clipping sent out by Dr. Kendall who is prominently connected with the Christian Home Orphanage, Council Bluffs, Iowa. Milk is surely better than medicine for almost everybody.

The most certain method ever adopted for the cure of the "great white plague" is through the diet used as per directions below, which can be taken at home,

and comes within the reach of the poor as well as the rich. The *modus operandi* is to force the body to take on fat—a desideratum long felt by the medical profession, but never before attained to.

During the last fifteen years I have prescribed this diet in hundreds of instances; and where directions have been followed strictly it has raised the weight and increased the strength and vitality of the patient rapidly up to a normal condition, thus enabling nature to assert her sovereign right to be the dominating force in the body, and the germs causing consumption have been overcome and the cure accomplished. Some have gained a pound a day, and would gradually take on less until they would not increase in weight any more.

The all-important thing is to drink large quantities of milk strippings (the very last of the milking). This seems so simple and easy that many have refused to follow directions, and demanded medicines to cure them; but there has not yet been discovered any medicine that is a specific for consumption.

To get best results a healthy cow should be selected, one that does not cough, and one that gives very rich milk. A Jersey cow is preferable. The milk should always be tested to be sure that there is a large per cent of cream in it.

The last quart should be milked into a separate dish which rests in a larger vessel containing warm water, just sufficient to prevent the strippings from cooling below blood heat. The cow should be thoroughly cleaned to prevent any dirt getting into the milk, so the patient can blow back the froth and drink at once without straining, as this cools it too much.

Begin by drinking nearly a pint in the morning and the same at night, and increase the quantity gradually so that in ten or fifteen days a full quart will be taken twice a day. It should be taken immediately after milking, before it has had time to cool any. All should be taken that can be without too much discomfort, and then rest two or three minutes, and drink more and rest again, and so on until a full quart has been taken as soon as it can be conveniently. In about fifteen minutes the patient should eat at the table such articles of food as are known to agree with the stomach. At noon eat as usual.

When the strippings are not allowed to cool below blood heat, and taken immediately after it is milked, a full quart will be transfused into the circulation in a remarkably short time.

I have never seen a case but could take the strippings without any discomfort worth mentioning when above directions were followed strictly, although some have declared they could not before trying it; but when they delayed taking for half an hour and the milk had cooled ten degrees I have seen half a pint make them very sick. The great secret of success with it is in taking it immediately after milking and not allowing it to cool below blood heat, taking a full quart morning and evening, and having milk that is very rich.

The following is a typical case. Mrs. A. E. was suddenly startled to find her weight was forty pounds below normal. She was coughing terribly, and soon had a very profuse hemorrhage from the lungs that came near taking her life. I at once began the use of the milk strippings after hemorrhage was stopped, and in about ten or fifteen days she had gained nearly a pound a day, and was soon able to get out of bed and go around the house. She increased quite rapidly; and as her weight and strength increased her cough decreased. When she had gained thirty pounds in about three months her cough had left her. I had her continue the same diet for six or eight weeks longer, and she gained ten pounds more, and then took on no more flesh. She was then as well as she ever had been, and continued well after the strippings were discontinued.

She took no medicine after the hemorrhage was stopped, excepting a little pepsin and some other remedies to aid digestion, and a simple cough remedy to ease the cough; but tar, lobelia, opium, tartar emetic, and such medicines as disturb the stomach and interfere with digestion were carefully avoided.

It is easy for those on a farm to carry out this method; and on several occasions parties who lived in the city purchased a suitable cow, and, after complete recovery in every instance, they sold the cow for nearly as much as was paid for her.

I do not remember any patient who followed the directions strictly who was not cured; but several persisted in declaring they could not take it, until so much valuable time wasted that they lost their lives.

I have found the same diet, when these directions were carried out carefully, to increase the weight and strength of those run down from other causes.

By E. R. ROOT.

### PROSPECTS FOR MOUNTAIN-SAGE HONEY UNFAVORABLE.

MR. L. E. MERCER, one of the prominent bee-keepers of Ventura, Cal., referring to the prospects for California sage honey for the year 1910, writes: "The sage is growing very slowly, and every one says no honey this year. Of course it is too early yet to tell to any certainty, but it doesn't look good to me."

One or two other reports have been to the same effect.

### THE PREVALENCE OF HONEY-DEW DURING THE YEAR 1910.

THE following letter from Dr. E. F. Phillips, of the Bureau of Entomology, will explain:

*Dear Mr. Root:*—Since honey-dew was so abundant in many parts of the eastern United States during the past season, it would be well for the bee-keeping industry to know, if possible, what conditions brought this on. I should very much appreciate it if the readers of GLEANINGS who had honey-dew last year would answer the following questions, and in addition give any facts which might help in solving this problem.

Was there any honey-flow from flowers?  
Did bees work on honey-dew and flowers at the same time?

What was the average amount of honey-dew per colony?

On what kind of tree or trees were the insects which produced the honey-dew?

Give dates showing the duration of the honey-dew yield.

Was much honey-dew used for winter stores?

Is the mortality of colonies up to the present date greater than usual among your own and neighboring bees?

What information have you as to the extent of territory in which honey-dew was abundant?

Replies may be directed to the Bureau of Entomology, Washington, D. C.

E. F. PHILLIPS,  
In Charge of Apiculture.

Washington, D. C., Feb. 19, 1910.

### CORRUGATED-PAPER SHIPPING-CASES FOR COMB HONEY.

IN this issue, in his department, "Bee-Keeping in the Southwest," Mr. Scholl mentions a lot of honey that was badly damaged in the corrugated-paper shipping-cases, while that in the same shipment in ordinary wooden cases came through with little injury. Mr. J. E. Crane, on the other hand, continues to ship his honey in the paper

cases, and has no fault to find with them, his buyers even paying him more for honey in the paper cases than in wooden ones. If we are not mistaken Mr. Crane encloses each section in a carton before putting it into the case, so that there is an additional cushion, so to speak, besides the regular corrugated partitions that divide each row of sections both ways of the case. In giving reports of the results of shipments sent in paper cases we believe that it should be stated whether cartons are used for each section, and also whether cases are used made like those advocated by Mr. Crane. If breakage occurs, the paper case should not necessarily be blamed unless Mr. Crane's directions have been followed to the letter. We do not know whether cartons were used for the honey referred to by Mr. Scholl, and we are not sure that their use would have resulted in the safe arrival of the honey; but the construction of the case may have had something to do with the breakage. Since Mr. Crane apparently has no breakage, it would be well to make sure that every detail is as recommended by him.

### WINTERING OF BEES UP TO THIS DATE.

WE have just looked over quite a number of our colonies at the home yard, wintered on their summer stands in double-walled packed hives. After the severe cold of the winter that has continued for these many days without a flight since the first of December (and our bees have not had a flight yet), we naturally expected to find a good many dead colonies, and the strong ones weak and suffering from dysentery. But we are happily surprised. We never saw bees in better condition than they are this 26th day of February. All colonies, both under sealed covers and absorbing cushions, are in fine order—exceptionally so. Not a single colony thus far has been lost, and in our preliminary examination we picked out all the weak ones, and those that were made up and fed late. All of them, strong and weak, were in excellent condition; and unless we have a very late spring, with warm days alternating with chilly, cold, and snowy days, there will be very little loss worth speaking of.

Reports from Michigan indicate excellent wintering, and a few scattering reports from Wisconsin show the same condition. A few stray reports from Pennsylvania and Indiana indicate a few winter losses.

Our neighbor, Mr. Wilde, some six or seven miles west of us has lost only three colonies out of one hundred; and while there are some few weak ones he says the rest of the colonies are doing well.

This has been an exceedingly favorable winter for cellar or indoor wintering; that is to say, it has been easy to control the temperature. For that reason we shall expect all inside wintering to show up even better than those wintered outside.

*Later.*—Since writing the foregoing we have received a number of reports from various sections of the United States. The indications are that the mortality will be very heavy among bees having nothing but honey-dew, wintered in single-walled hives. Honey dew stores in outdoor colonies well packed in winter cases or double-walled hives, in the more northern sections of the country, do not necessarily seem to be fatal. Indeed, the reports from most of our northern States, where the bees were properly put up outdoors or indoors, are fairly good. Some reports go to indicate that there is good and bad wintering in about latitude 35 to 40 and east of the Mississippi River. Where the colonies were fed sugar syrup and the old honey dew was covered up, there appear to be no great losses. But pure honey-dew in single-walled hives, unless the hives are located pretty well south, seems to have disastrous effects.

#### THE RELATION OF CLOVER TO SNOW.

The large amount of snow that has fallen all over the northern section of the country, and has stayed on the ground almost throughout the entire winter, will mean a luxuriant and heavy growth of clovers this coming summer. The ground has been thoroughly watered, and the plants have been protected as they have not been before in years.

In this connection it is pleasant to remember that, years ago, when we used to have these old-fashioned winters, such as we had this year, we had "old-fashioned honey-flows," that is, there was a flow of clover honey every year; but these open winters seem to have an adverse effect upon the clovers, in that there is a great deal more winter-killing than when the winter is more severe and continued, with snow. Taking it all in all, we are exceedingly hopeful of the outlook for the coming summer.

#### ADULTERATORS BEING BROUGHT TO TIME.

THE Department of Agriculture, Washington, D. C., is bringing some of the adulterators and misbranders of food products and drugs to time. Some of the specific offenses are as follows: Misbranding strawberry extract, adulteration of lemon extract, misbranding drug preparations, adulteration and misbranding of vanilla and lemon extract, selling of rotten peaches, misbranding of liquors misbranding of maple, adulteration of seedless raisins, misbranding of evaporated apples, misbranding of cheese, of baking-

powder, of pepper, and powdered assafoetida.

May the good work go on! There is a great deal more that Uncle Sam ought to do, could do, and would do, if that prince of pure-food exponents Dr. Harvey W. Wiley, of the Bureau of Chemistry, could have his way. The fact is, he seems to be overruled by his colleagues, who are in the majority.

On the other hand, we have reason to know that there is very little if any misbranding or adulteration of honey. We have traveled over a good portion of this country, and have been keeping, as we believe, in fairly close touch with the great market centers, and we do not hear or know of any adulterated honey of any sort, and we do not believe there is any, a magazine article to the contrary.

#### PRICE OF HONEY; SOME REASONS WHY IT DOES NOT KEEP PACE WITH THE ADVANCES OF OTHER FOOD PRODUCTS.

THERE is one point that perhaps has not been touched upon by our correspondents in the general discussion that has appeared in our columns during the last two or three issues. Say what we may, the fact is that the price of *all* sugars, syrups, and sweets in general have maintained about the same level for years back. The price of honey is dependent *somewhat* upon the price of other sweets, like maple syrup, granulated sugar, brown sugar, and New Orleans molasses. The facts are, for the last ten years there has been very little fluctuation in the price of these commodities. The probabilities are that, if there had not been a general advance in general food stuffs, the price of sugar and the different grades of molasses would have decreased.\* So long as a standard table article like maple molasses, one of the finest products that was ever sold, remains stationary, extracted honey can not go much above its present figures, for the dear public will not pay too high a price for mere flavor, or at least until it is educated to the fact that honey is a predigested sweet, more easily assimilated than the ordinary cane sugars and syrups on the market. We do not mention the different classes of glucose or the so-called corn syrups, as we do not for a moment consider them in our class.

Maple syrup is an article produced only in very limited areas in the United States—one section in Northern Ohio, another in Michigan, and still another in Vermont. There are a few other places where limited quantities are produced; but the three first mentioned produce the great bulk of the maple syrup that is made in this country. This means that the genuine maple syrup, a boiled-down sap of maple trees, has a very limited production. The amount annually turned out is very small in comparison to the annual production of extracted honey alone, to say nothing of that produced in the comb. Yet notwithstanding that, and the further

\* Its production has increased faster in proportion than the population.

fact that it is the finest table syrup, outside of honey, that was ever produced, it has been selling for the last twenty years or more at the old regulation price of \$1 00 a gallon, and is still selling at that price. Sometimes it reaches the figure of \$.25, but this is very rare. The price soon gravitates down to \$1 00 and stays there.

This is more remarkable when we consider the fact that the national pure-food law has practically stopped the selling of all adulterated syrups bearing the name maple syrup. This means that the competition of the adulterated goods has been eliminated except for that syrup bearing the name of "mapleine," which seems to be a legitimate product—a cane syrup flavored from an extract from maple wood. In spite of the limited production of maple syrup, and the fact that it has almost no competitor in the field except honey, it is remarkable that the price hovers around the dollar mark year in and year out, notwithstanding all staple articles of food, outside of sugars, have advanced in price. Unless there should be a marked advance in the price of the general sugars, and that does not seem probable, in view of the vastly increased production, we probably can not expect any very marked increase in the price of ordinary extracted, although there will be some increase, especially among the finer grades of comb honey.

#### OHIO FOUL-BROOD LEGISLATION.

PROBABLY before this journal is in the hands of the reader an effective State-wide foul-brood bill having the general features of the model law recommended by Dr. E. F. Phillips, of the Bureau of Entomology, will be before the legislature. Senator Pearson will introduce the bill.

Ohio has had for a number of years a foul-brood law, but it is based on what is known as the county plan; and, as we have before explained in these columns, it is a dead letter. The county plan of fighting foul brood has always been a failure except where the counties are very large, as they are in some of the Western States.

This bill has the sanction and support of the Ohio State Bee-keepers' Association; the Southwestern and Hamilton Co. Bee-keepers' Association; Secreary Sandes, of the Ohio State Board of Agriculture; State Entomologist Shaw, of the Department of Agriculture, and all the bee-keepers of the State. This law calls for no appropriation, because the Department of Agriculture will assume the expense if we will only give it police authority to carry its provisions into execution. The following is the text of the bill that is to be introduced within a few days.

#### AN ACT

*To establish a Division of Apiary Inspection in the Ohio Department of Agriculture, and to repeal certain sections herein named.*

SECTION 1. The Ohio State Board of Agriculture is hereby authorized to establish a Division of Apiary Inspection in the Ohio Department of Agriculture, and to appoint a competent entomologist as the chief inspector of said division, and the necessary assist-

ants, who shall, under the direction of the board, have charge of the inspection of apiaries as hereinafter provided; he may investigate, or cause to be investigated, apiaries as herein after provided; he may investigate, or cause to be investigated, outbreaks of bee diseases, and cause suitable measures to be taken for their eradication or control.

SEC. 2. The inspector or his assistants shall, when notified in writing by the owner of an apiary, or by any three disinterested tax-payers, examine all reported apiaries, and all others in the same locality not reported, and ascertain whether or not the diseases known as American foul brood or European foul brood, or any other disease which is infectious or contagious in its nature, and injurious to honey-bees in their egg, larval, pupal, or adult stages, exists in such apiaries; and if satisfied of the existence of any such diseases he shall give the owners or care-takers of the diseased apiaries full instructions how to treat such cases as, in the inspector's judgment, seem best.

SEC. 3. The inspector or his assistant shall visit all diseased apiaries a second time, after ten days, and, if need be, burn all colonies of bees that he may find not cured of such disease, and all honey and appliances which would spread disease, without recompense to the owner, lessee, or agent thereof.

SEC. 4. If the owner of an apiary, honey, or appliances, wherein disease exists, shall sell, barter, or give away, or move without the consent of the inspector, any diseased bees (be they queens or workers), colonies, honey, or appliances, or expose other bees to the danger of such disease, said owner shall, on conviction thereof, be fined not less than fifty dollars nor more than one hundred dollars, or imprisoned not less than one month nor more than two months, or both.

SEC. 5. For the enforcement of the provisions of this act the State Inspector of Apiaries or his duly authorized assistants shall have access, ingress, and egress to all apiaries or places where bees are kept; and any person or persons who shall resist, impede, or hinder in any way the inspector of apiaries in the discharge of his duties under the provisions of this act shall, on conviction thereof, be fined not less than fifty dollars nor more than one hundred dollars, or imprisoned not less than one month, nor more than two months, or both.

SEC. 6. After inspecting infected hives or fixtures, or handling diseased bees, the inspector or his assistant shall, before leaving the premises, or proceeding to any other apiary, thoroughly disinfect any portion of his own person and clothing, and any tools or appliances used by him, which have come in contact with infected material, and shall see that any assistant or assistants with him have likewise thoroughly disinfected their persons and clothing and any tools and implements used by them.

SEC. 7. It shall be the duty of any person in the State of Ohio, who is engaged in the rearing of queen-bees for sale, to use honey in the making of candy for use in mailing-cage which has been boiled for at least thirty minutes. Any such person engaged in the rearing of queen-bees shall have his queen-rearing apiary or apiaries inspected at least twice each summer season; and on the discovery of the existence of any disease which is infectious or contagious in its nature, and injurious to bees in their egg, larval, pupal, or adult stages, said person shall at once cease to ship queen-bees from such diseased apiary until the inspector of apiaries shall declare the said apiary free from all disease. Any person engaged in the rearing of queens who violates the provisions of this section, shall, on conviction thereof, be fined not less than one hundred dollars nor more than two hundred dollars.

SEC. 8. The Ohio State Board of Agriculture shall make an annual report to the Governor of the State concerning the operations of the Division of Apiary Inspection, which shall give the number of apiaries inspected, the number of colonies treated and destroyed by the direction of the Chief Inspector, and such other information as may be deemed necessary.

SEC. 9. Sections 5853, 5854, 5855, 5856, 5857, 5858, 5859, 13368, 5860, 5861, 5862, 5863, and 5870 of the General Code of Ohio are hereby repealed.

It is very important that every bee-keeper write his Representative and Senator at once, urging their support. If you do not know who they are, inquire of your postmaster, the editor of your local paper, or of some lawyer. If possible, get a response from both, signifying their support.

## STRAY STRAWS

BY DR. C. C. MILLER, MARENGO, ILL.

THE MAN who owns a piece of land does *not* own the nectar on it. Prof. Cook first made that assertion, and I defy any one to contradict it successfully.

F. GREINER, page 107, tells how to make a Miller feeder so that the bees can entirely empty it. Here's another way: Instead of having it in two compartments, make it in one large compartment (as most of mine are made), the bees going up each side. No matter how crooked the hives stand, the bees can get the last drop.

ALIN CAILLAS, *L'Apiculteur*, 97, thinks the discovery that infinitesimal quantities of radium are found in some honeys, not in all, may have much importance medicinally. Not only may it affect lupus and cancer, but the enfeebled, the neurasthenic, and convalescents may feel its benefits. If manufactured radium has proven valuable, he asks whether it may not be more so when taken in its natural state.

LUTHER HACKLEMAN thinks bees are not the heartless creatures they are supposed to be. He watched a worker carrying out a wounded comrade. She dropped with her burden near the hive; but, instead of leaving it heartlessly to its fate, she first *fed it*, and then flew off, as if saying, "Good by, God bless you!" [If she fed it, did not such feeding prolong the misery of the bee that must necessarily starve to death?—ED.]

ADRIAN GETAZ has my hearty thanks for telling me what crazy work I did in changing from square kilometers to our square miles. That Straw, p. 68, should say that in the German Empire the average is 2.86 colonies to the square mile, ranging from 1.43 to 6.56; and with apiaries three miles apart the average apiary would have 25.74 colonies, and in the most densely occupied regions there would be 59 colonies to the apiary. A smaller hat would now fit me!

COMB HONEY, in this locality, doesn't need the heat and even temperature mentioned for alfalfa, page 135. Sections piled near the furnace stood through the winter of 1908 and through this winter so far without granulation, the temperature ranging from 40 to 80, and the door open a good deal of the time. [Any comb honey kept in a warm place for a time will resist the effect of changing temperature better than comb honey that has not been so treated. White-clover honey is much more proof against candying than alfalfa.—ED.]

MONSIEUR G. MARTINET, chief of the federal establishment of seeds at Lausanne, among the red-clover plants he had under selection noticed two or three kinds that were specially visited by honey-bees. He placed them, with others, under a cage of coarse cloth which contained a hive of bees, excluding bumble bees and other insects. One kind was especially visited by the bees,

and showed a harvest of seed as great as plants of the same kind in another cage containing bumble-bees, and even greater. It is believed that rigorous genealogical selection will perfect and fix the type, thus producing a pure race of red-clover capable of fertilization by honey-bees. This special variety being a great producer, the hope is to increase the yield of clover, and at the same time the yield of honey. Moreover, there is complaint of a general disappearance of bumble-bees; and with this new variety and plenty of hive-bees, red clover will be a reliable crop.

THANKS, Messrs Taylor, Holtermann, and Whitney, for contributions to the territory problem, page 154 and following. Now can't you three or some one else put your heads together and help me out? Here's my fix: I would like to keep bees; can't do it without pasture; am told I have neither legal nor moral right to any, and would like by some honorable and honest means to have both. Two of you only tangle me up worse than ever by flinging questions at me. Bro. Taylor alone considers my need, tells me there is a way to obtain territory for pasture, and says, "There is no other way." Good. That is just the way I'll do, then. So I get "a fee simple" in a tract of land two miles square, which, as he says, I own clear through from heaven above clear down to where I never expect to make a permanent residence, and settle down safe in his assurance that no one can dispossess me of the right to keep bees there without my consent. But soon I am disillusioned, for from the apiaries on all sides come streaming bees of other men that promptly "dispossess" me of the nectar on my land, and I have no redress. And now I see the lawyer's trick. R. L. Taylor, I asked for the right to *pasture*, and, in reply, you tell me I can have the right "to keep bees," a right that I had before, and that every one now has who commands a few feet of land. It seems that bee pasture is free to all, just like that Montana cow-pasture Bro. Taylor tells about, and just like much of the cow-pasture in Illinois when I first came here. But that wasn't the best way for the general good, and so Uncle Sam parceled out the land to individual owners. Now, here's the bee-pasture, exactly parallel to the case of the cow-pasture—free to all, with no sole owners. Why can't Uncle Sam do with the bee-pasture just as he did with the cow-pasture? He would thus make a little out of it for himself, make keeping bees as reliable as keeping cows, and do a good thing for the country in general. [The control of bee-territory is an old mooted question. Notwithstanding it has been ably discussed in our back volumes and in late issues of this journal by able men, it seems no nearer solution than it was twenty years. When lawyers and doctors disagree, who shall decide? Unless there shall be some very good reason, we would prefer to have the discussion drawn to a close for the present, especially as the "last say" is so short. *Requiescat in pace*.—ED.]

## SIFTINGS.

By J. E. CRANE, MIDDLEBURY, VT.

I do not quite like Carey Rees' method, p. 767, Dec. 15, of locating hives; for the more compact we can place them, the less traveling we have to do. Besides, what is gained in having the house in the exact center if one has to carry all the honey to one side when moved away?

On page 730, Dec. 1, I believe Mr. Hand has the better of the argument with Mr. Greiner on the use of full sheets of foundation in sections. We bee keepers know that honey in comb built entirely by the bees is preferable to that built on ordinary thin foundation. We also know that it is much more profitable to use full sheets of foundation; and until dealers and consumers are willing to pay us the difference we shall continue to use the full sheets.

The origin of honey-dew, by D. M. Macdonald, taken from the *British Bee Journal*, page 764, Dec. 15, is of great interest at this time. While it may be true that plants do exude a sweet fluid that bees gather, I believe the great bulk of dew, so called, is an insect product, much inferior to that gathered from the flowers by the bees. The practical question seems to be the best use to make of such sweet. He names various uses, to which I would add that of printer's ink, as I understand a large amount of low-grade honey is used for this purpose. He suggests using it for spring feeding, which is, perhaps, the best suggestion of all, although I can not agree with him that it is as good as the very best grade of honey in the market for turning into bees; yet I know it will answer a very good purpose, for I have used many hundred or thousands of pounds in this way.

I can not agree with Mr. Tricky, of Nevada, page 723, Dec. 1, in what he says regarding the use of plain sections. We have used plain sections for many years without trouble. It may make some difference, however, from the fact that we use cartons on all our sections.

We notice that Mr. Tricky has very pronounced opinions as to the paper case being too weak to stand up with its load in carload shipments. I am not surprised that he should feel this way or that such should be his first impression, for at first I felt the same. For years I thought of this material as being very desirable for a shipping case, but could not make myself believe that a paper case could be made that would stand packing in a car and carry the load of honey safely. Therefore I placed the corrugated partitions at first inside of a wooden case to make it strong enough, and after months of study I made up my mind that paper cases were theoretically strong enough, and so I had some 500 cases made. Yet it was with a good deal of

fear that I shipped my first honey in this way; but after four seasons' trial I have no fault to find with them, and dealers are still paying us more for honey packed in the paper cases than in the wooden ones. [See editorial elsewhere.—Ed.]

Automobiles for bee keepers, page 557, are of considerable importance to those running outyards. For instance, we have six outyards that we expect to visit once in six or eight days, and spend a day at each yard. To go to all these yards and back makes a total distance of 90 miles; traveling with a horse at five miles an hour would take 18 hours, but in practice a good deal more than that, for many of the roads are quite hilly. An automobile would travel the whole distance in less than half the time, so that we could take care of another yard, or give those we already have much better care than they now get. We have not yet purchased a car, but have in mind a trucking car called "The Rapid" that will travel 10 to 18 miles an hour, and carry 1500 to 2000 lbs. load. It is used, I believe, more largely in the East for heavy work than any other, and perhaps all others together. It is manufactured by the Rapid Motor Vehicle Co., Pontiac, Mich.

On page 727, Dec. 1, Doolittle tells us how to lay out an apiary, and he says that of late he uses four half-bricks for a foundation under his cleated bottom-board. This is all very well so far as it goes, and it may answer the purpose where the colonies are wintered in a cellar and the bricks changed to a new location every season; but when a hive stands in the same place the year round, half-bricks go into the ground very quickly, letting the hives follow. We have found good-sized stones preferable. Some have recommended cement, and I think this might do in many cases. Last spring, in underpinning some for y hives we used slabs of marble six or eight inches wide by one or two feet long and two or three inches thick.

Placing the hives in hexagonal groups is not a bad idea if they are set far enough apart. I located a yard in this way some thirty years ago, but had the hives only six feet apart, and I lost too many queens. Ten feet apart would probably be all right; but the yard takes rather too much room. I like to have the hives in groups, either six, eight, or ten in a group, and then have each group painted a different color.

Mr. Doolittle wisely objects to hives facing the north—an objection which is well taken unless in well-sheltered places. This reminds me that nothing is said about locating the yard in a sheltered place out of the wind. To my mind, this is the most important point of all, especially when the colonies are wintered out of doors. Never locate a yard of bees where it is necessary to place stones on the covers to keep them from blowing off. Also never locate the hives where the snow drifts badly. We have two yards in such places, but we intend to move them soon.

## BEE-KEEPING IN THE SOUTHWEST

BY LOUIS SCHOLL, NEW BRAUNFELS, TEX.

Dr. Miller, that old comb with the  $\frac{1}{2}$ -inch midrib produced dwarf worker bees, and this means that that particular comb had become unprofitable on account of age. This is my point. You are changing points by trying to get me to space the combs further apart—something which the bees can not do.

Plenty of good rains and lots of cold weather, with the ground covered with snow for a few days this winter, have made the prospects in most parts of Texas the best we have had for many years. It is reported that the prospects are not so favorable in Southwest Texas, where the bulk of the honey is produced.

### OLD TEXAS VETERAN.

It was my good pleasure last summer to meet one of the oldest, if not *the* oldest, bee-keepers in Texas—Mr. M. S. Klum, of Jacksboro. He came to Texas in 1869, soon after becoming the possessor of bees, and since that time he has kept from 25 to 90 colonies. It has been interesting to hear Mr. Klum relate some of his early bee-keeping experiences. He told in detail about the beginning of GLEANINGS; how he obtained the first four numbers through a special subscription privilege given by Mr. A. I. Root; and how certain changes were made, first to a monthly and then to a semi-monthly. Through all the years he has been a subscriber to GLEANINGS, and he recently sent all the volumes to me except some of the very earliest, which had been destroyed during a fire, and I have added them to my library. Mr. Klum is one of the charter members of the first Texas bee keepers' association, which was organized in 1877 at McKinney, in Northern Texas, and is the only survivor. While he still has bees and takes a great interest in them, he is not able to give them the care that he formerly did. I honor these aged men to whom we owe so much. They went over the rough trails before us and made our paths smooth.

### CORRUGATED-PAPER SHIPPING-CASES.

We regret to say that these paper cases did not prove very successful in a trial shipment which we made a short time ago. Eighteen cases of section honey were sent by express from a point in Western Texas to W. H. Laws, at Dallas. Of the eighteen cases, two were of corrugated paper, while sixteen were regular glass-front wooden cases. The paper cases were properly marked, but the wooden cases were not, for the glass fronts showed the contents. At first thought, one would suppose, after examining the two different kinds, that the corrugated-paper cases would be far ahead

of the old style; but the reverse proved to be the case in this shipment. Of the sixteen old style cases of sections there were hardly enough broken ones to fill one case; but in the paper cases the sections were not only all broken, but they were smashed and even the cases themselves were badly crushed. They were in such bad shape that we did not even open them to remove the contents, as all was a total loss. The paper was soaked with honey. An examination of the few broken sections in the other cases showed that most of the combs that did not stand the shipment were not well attached to the wood of the sections.

It is not our intention here to denounce paper shipping-cases; but from the result of this experience we should like to warn others to try only a few of them before investing too deeply. We know that we would regret it if we lost a fine crop of comb honey on account of improper carriers. It is possible that the above is an exceptional case; but it is well to err on the safe side. We also give this experience for the benefit of the advocates of this case so they may be enabled to make further improvements if necessary. [See editorial.—Ed.]

### THAT CHUNK-HONEY EDITORIAL.

That abstract from Mr. Cady's article and the comments made by the editor, p. 33, would make it appear that we Southerners did not understand the situation regarding bulk comb honey in the North as compared with that in the South. It might be well to explain, however, that we are well aware that the North is not at all ready to take to such honey in any great amount; that the people will have to be educated to it first, and that even the bee-keepers will have to educate themselves in the matter as to the best methods to adopt in its production, its care, and putting up for the market, and, finally, the best ways of marketing. We understand all this, perhaps better than the bee-keepers, and the consumers of the North understand our position. We know that it will take time to introduce such an article in the North—that it can not be put off on the public in a wholesale manner right at the very start, without playing sad havoc in the future sales of the article. This was the entire trouble with Mr. Cady's experiment. Instead of letting a "silver-tongued hustler" put off on the inexperienced public in glorifying terms an article that was new, and that was not understood, it would have been much better to introduce it in a small way at first, letting it find a market of its own slowly, which would finally have reached great proportions, perhaps. If not, then the bee keeper is not out much for the small investment in giving it a fair trial. The case referred to is only one of hundreds that have failed because a new thing was lauded beyond the expectations of the buyer. It teaches us a valuable lesson, however, that we should go slow at first when trying new things.

## CONVERSATIONS WITH DOOLITTLE

AT BORODINO, NEW YORK.

### DO OUT-APIARIES PAY?

"My bees have increased till I have more than I think it profitable to keep in one place, and I came to have a little talk with you about moving a part of these colonies to a place four miles away, where I think the location fully as good as it is where I am. Do you think such a course would pay me?"

"How many colonies have you now, Mr. Morgan?"

"I have 300; and I thought if I could move 100 of them to the place I spoke of it might be better to do so. I must either do this, be overstocked, or sell a part of my bees. At least that is the way I look at it."

"Well, you should know your location better than any one else. Mr. Alexander kept 700 colonies at one place, and did not think his locality overstocked. There are possibly some few localities where 500 to 700 colonies could be kept with a profit, and there are others where 100 colonies would be too many to make a success. For myself, I should consider from 100 to 200 colonies as many as it would be profitable to keep in the average apiary; and if I wanted to keep more I would rather start an out-apiary than to sell all the bees I had above that number."

"That is just what I had hoped you would tell me. Now, how many colonies would you use for an out-apiary?"

"Fifty colonies would make a good start until you could be sure that more would do as well. But this would depend somewhat on how near your own or other bees the apiary was to be established. Of course, if you could go seven or eight miles from any other bees, the out-apiary should do as well as your home yard provided the pasturage were the same. But as a rule I should think 100 colonies would be as many as would be profitable, especially if the out-apiary is located within four miles of the home yard."

"Then, according to what you say, I could divide the 100 which I do not think best to keep at home, and start two out-apiaries; and if I found that each yard of 50 did well, increase them to 100 later on."

"That would be my way of doing it."

"Then that is what I will do as there is a place four miles in a direction opposite my home, which, so far as I know, is as good as the other. But don't you think I had better have some one to look after swarms during the summer months?"

"If you are to increase your bees by natural swarming, this will be necessary; but if you work them as given in 'A Year's Work in an Out-apiary' you should not have swarms enough to pay for the keep of any one. I have not had anybody to look after the bees in the out-apiary for more than ten years; and so far as I know, only two swarms have gone off in all that time. One colony became strong in apple bloom before I put on the up-

per hives, then swarmed; and the swarm got away, as the queen in this case was unclipped, and there was no one to give it a home. Then I had another case where a colony had swarmed several times before I was ready to shake for the first time; and after shaking they built queen-cells and swarmed, without trying for any worker brood. This they kept up, evidently, till I went for the second or final shaking for the year, when they swarmed while I was there, thus telling their secret. However, this was evidently a case of supercedure, as the queen did not lay to the amount of two frames of brood at erward."

"But if I stop all swarming, how shall I increase?"

"When you get home, turn to Chap. V. in the out-apiary book, and that will tell you how you can make all the colonies you may desire, and that, too, with little or no cost to you in honey."

"Then, should I wish to continue out-apiaries still further than the two, I could make all the colonies I wish by what is given in Chap. V., and not depend on natural swarming at all."

"Certainly. The day of natural swarming for increase has gone by, so to speak; for if I am right, few of our most practical apiarists allow little if any swarming, whether at home or in the out-apiary."

"Well, should I conclude in the future to run several out-apiaries how would you locate them?"

"The amount of pasturage should be the first thing to consult. Next is the most convenient way to reach these out-apiaries. If you are to use horses or the automobile as a means of conveyance I would locate an apiary from five to seven miles from my home, as near the four points of the compass as possible, if the location would permit of my doing this; and a fifth one in some good location five miles away from any of these four. I would have five out-apiaries if I could possibly do the work, and in this way I could attend to an apiary each working day of the week, including the one at home."

"When the home yard is located near a trolley line it would be the greatest of fun to locate apiaries at the best locations along this line for in this way they could be reached at any half-hour. How much should I pay as rent for the ground?"

"There can be no set price for this. In one case I knew of, the man having a fruit-farm, he welcomed the bees without making any charge, considering that he was indebted to the apiarist for the good the bees did as fertilizers of the blossoms of his orchards. Most men, however, want from \$5.00 to \$10.00 a year. And now may I let you into a little secret? Whatever the price agreed upon, when the end of each honey season arrives, make the person whose land you occupy a present of from twenty to thirty pounds of nice honey; and if your experience proves like that of mine you will have a fast friend for all time, with no complaint of the bees being a nuisance, even should they be somewhat troublesome at times."

# GENERAL CORRESPONDENCE

## THE SOURCE OF HONEY-DEW.

### D. M. Macdonald's Opinions Disputed.

BY DR. C. GORDON HEWITT,  
*Dominion Entomologist.*

[This article by Dr. Hewitt, and the one which follows it, by Dr. E. F. Phillips, were received by us at practically the same time. Both writers agree very well in regard to the source of honey-dew, and, coming from such authorities, we feel quite sure that these opinions, together with that from Prof. H. A. Surface, may be taken as the final answer to the question, viz., that most of our honey-dew is an excretion from the aphides.—Ed.]

I have read with interest the recent communications in GLEANINGS on the above subject which appears to have been stimulated by the remarks of Prof. H. A. Surface in your issue of October 15, p. 623. In your issue of December 15, p. 763, an article by Mr. D. M. Macdonald, in the *British Bee Journal*, was published which tended to disprove the views of Prof. Surface; and in the last issue of your journal which I have just received, Feb. 1, p. 89, Mr. J. L. Byer expresses the pleasure that he will feel should Mr. Macdonald's view be established—namely, that honey-dew is not an excretion.

It is a matter of regret that there should be any doubt in the minds of your readers as to the nature and source of the honey dew in aphides, as this has been established as a scientific fact for many years: and it is on this account, and in order to set the matter at rest in the minds of those who may not have the advantage of being acquainted with the scientific literature on the subject, that I am taking this opportunity of placing the true facts before your readers.

Some writers have believed that the sugary matter called "honey-dew" was produced (I will refer to the use of the two terms "secreted" and "excreted" later) by the pair of peculiar tubes or siphons which exist in certain sub-families of the aphides: but it has been proved by many authorities that this view is erroneous. It has been shown that honey-dew is a product of the alimentary or digestive tract, and escapes by way of the anus, or vent. Certain species of aphides produce large quantities of honey-dew which is so prized by ants and certain other insects, including bees.

In the early half of the 18th century the famous entomologist Réaumur expressed the view that honey-dew does not issue from the siphons but from the anus; and, later, Kaltenbach supported the idea. Forel states definitely that the siphons do not secrete a sweet fluid but a gluey wax which is not sought by the ants: the sugary matter which they lick up is rather an excretory product of the digestive tract.

In 1891 Busgen observed a single individual produce 48 drops, each drop being about 1 mm. (i. e.,  $\frac{1}{25}$  of an inch) in diameter in 24

hours (p. 193, *Biologisches Centralblatt*, vol. 9). The production of this honey dew is also affected by the temperature; and Brandes (Die Blattlaus und der Honigbau, in *Zeitschr. für Naturwiss.*, vol. 66, pp. 98—103, 1894) found that the greatest activity was in the middle of the day. The fact of the effect of temperature on the production of honey-dew by the aphides is taken advantage of by certain species of ants which keep the aphides warm by erecting small tents or shelters over them which may be compared to cow-sheds.

In the article of Mr. Macdonald's, to which reference has been made, he says, p. 764, "It, like the honey-bee, has something in the nature of a honey-sac, quite separate from its ordinary stomach, and from which, when the sac gets overcharged, it regurgitates or rejects aphidian honey by means of two tubes used for *no other purpose*." Although the author of that statement may be an excellent bee-keeper he is not a scientific entomologist, or he would never have made such a statement, which is absolutely inaccurate. The honey-sac of the bee is the fore-stomach, and is part of the digestive tract. The digestive tract of the aphid has no connection with the two tubes or siphons by which it has been wrongly thought the honey-dew is produced. The gluey waxlike substance which appears in drops at the end of these tubes is secreted by a group of small gland cells situated at their bases. Certain aphides, such as the woolly aphid, chermes, etc., do not possess these siphons or tubes, but have, instead, simple pores on the upper side of the body which produce waxlike threads from wax-glands. If Mr. Macdonald will consult a paper by A. J. Grove, on "The Anatomy of *Siphonophora rosarum*, Walker, Part 1, the Apterous Viviparous State," in *Parasitology*, Vol. II., pp. 1—28, 1909, he will find two excellent figures of the alimentary or digestive canal of this rose aphid on page 7, from which he will see that it is a very simple structure.

Honey-dew is an excretory product of the digestive tract of the aphid which is naturally expelled by the usual aperture. It is elaborated in the digestive processes from the very large amount of sap which the aphids suck up by means of their proboscides; and as it can not be made use of by the insects in building up the body tissues and producing young, it is excreted in a changed form as a waste product. I entirely fail to understand why the idea of its being an excretion instead of a secretion should be repellant to any one: it is merely changed cell sap, as also is honey, both of which undergo a change in the digestive tract of the insect. The difference between an excretion and a secretion is really not so great as at first sight appears. The cells of an animal's body produce certain chemical substances according to their nature. The cells of the salivary glands produce by their activity a *secretion* known as the saliva; the wax-cells of the aphid and of the bee produce a wax *secretion*. Many of the cells of

the body extract waste substances from such of the body fluids as the blood, etc., and in turn excrete these substances into the digestive tract or the kidneys, or even, in the case of sweat-glands, on the skin of the animal. Both secretions and excretions may be the results of cell activity. Of course, the term excretion is frequently used to indicate waste products which have never gone through the cells but have passed through the alimentary canal in an unaffected state; that is not, however, cellular excretion.

I may add that, by observation, dissection, and microscopical examination these facts concerning the origin of honey-dew and the nature of the siphons or holes which were supposed to secrete the same have been confirmed by me.

Ottawa, Canada.

### THE SOURCE OF HONEY-DEW.

#### Most of It is in the Nature of an Excretion.

BY DR. E. F. PHILLIPS,

*In charge of Apiculture, Bureau of Entomology, Washington, D. C.*

The article on p. 763, Dec. 15, by the distinguished Scotch bee-keeper D. M. Macdonald, seems to call for further discussion of this subject. The past season has been a most remarkable one in bee-keeping on account of the excessive amount of honey-dew gathered by the bees, and equally remarkable by the scarcity of honey. The result is that most bee-keepers have on hand a quantity of honey-dew honey. Under such circumstances it is but natural that we should desire to have as good an opinion of the product as possible, for we want to eat it, and we desire also to be able to sell it under a good name. There are a few bee-keepers, however, who do not want the exact truth about the matter, even if it is not what their wishes might dictate.

Honey-dew is a general term, including sweet substances from several sources. There are many plants which have nectaries outside the flower which secrete honey-dew, which is gathered by bees. Among these may be mentioned the hau, of Hawaii (see Bulletin 75, Part V. of the Bureau of Entomology); cotton, some of the acacias, and confers. It is a mistake, however, to assume, as Mr. Macdonald does, that this is a characteristic of the majority of plants from which honey dew is gathered, for the greater proportion of honey-dew is not a plant secretion but an insect product.

Insect honey-dew is produced by various hemiptera, among which may be mentioned scale insects, aphids, and leaf-hoppers. The production of enormous quantities of honey-dew by a leaf-hopper in Hawaii is discussed in the bulletin referred to above. The insect honey-dew with which we have had to contend during the past season is derived from scale insects and aphids, and only observation can decide whether this is an excretion or a secretion from certain glands.

First of all, it can be stated that Mr. Mac-

donald is mistaken when he states that the plants secrete a sweet liquid on which the aphids come to feed. These insects, and scale insects also, feed only from the inside of the plant through sucking mouth parts. It is not necessary to offer proof on this point so well known to all entomologists. The only question to be considered is whether the sweet substance given off by these insects is an excretion from the anus, or whether it comes from certain glands through nectaries. The popular belief has long been that it is derived from the nectaries, and popular science furnishes beautiful tales of the "milking" of aphids by ants. Such writings are not always infallible.

Probably a large proportion of the honey-dew gathered by the bees this past season was derived from scale insects *which have no nectaries*. The honey-dew from this source is a pure excretion.

That the honey-dew of aphids is an excretion and not a secretion can readily be proven by any one interested enough to spend a few hours watching a group of these interesting insects. Drops of honey-dew will be seen to appear at the anal end of the insects, and then to drop as if forced from the body. This fact was noted as far back as 1800, and since that time has been observed and recorded by various entomologists. Another interesting test will be to secure one of the insects, holding it by the head between the thumb and finger and gently pinching it. Usually, if the insect is well fed a drop of clear sticky honey-dew will be forced out from the body at the anal opening; and if pinched hard the body juices will be forced out here, and also out through the nectaries.

Some groups among these insects will be with long prominent nectaries, and others will be found without nectaries or nectary pores.

The first group *secretes* or *excretes* from the nectaries a very small amount of a white liquid which is by many supposed to be the honey-dew of aphids. Even if honey-dew comes from the nectaries it is an excretion, or the casting-off of the waste products of metabolism for the liquid so ejected is not of use to the animal in any of its functions. Prof. C. P. Gillette, Canadian Entomologist for 1907, p. 236, states that "Neither he nor his helpers who have been observing the *Aphidæ* rather carefully for a few years past have ever found honey-dew issuing from the cornicles."

Among the second group (having no nectaries or nectary pores) some species live in galls formed on leaves; and often a gall, when fully developed, will be half filled with this excretion, and the aphids are probably saved from drowning only by the waxy secretion which is secreted by glands along the dorsal surface of the body. The fact that the species of this group do not have nectaries or even nectary pores, and yet excrete a large amount of honey-dew, is clear evidence that among them the honey-dew is excreted through the anal opening.

As the aphids usually feed on the under

side of the leaves, and when present in numbers excrete a large amount of honey-dew, naturally the honey-dew falls on to the leaves lower down, which are soon covered with a sticky substance.

All observations up to the present time indicate that the honey-dew of aphids is an *excretion* passed through the digestive organs of the body, and is a residue of the juices sucked from the various food plants for the purpose of food.

That smut grows on honey-dew can not be contradicted, and possibly Mr. Macdonald is correct in attributing the dark color of honey-dew honey to such a cause. He is not correct, however, in his assertions that honey-dew is largely a plant secretion and in part a secretion from the nectaries of aphids.

---

### FEEDING POLLEN SUBSTITUTES IN EARLY SPRING.

#### Is it Desirable? an Interesting Series of Experiments.

BY SAMUEL SIMMINS.

This subject was brought forward in GLEANINGS during 1909, and some of those who have found an occasional deficiency of natural pollen in the early season gave their experiences in supplying substitutes. Over a course of many years I have given this subject much thought and careful experiment. A common practice in Great Britain is that of dusting pea flour on to pine shavings placed in a box, or in an inverted hive arranged in some sheltered sunny corner as soon as springlike weather is in evidence, when a merry hum and happy industry gladden the heart of the enthusiastic if not too observant bee-keeper.

Very few owners have so far realized that this practice is fraught with danger, especially when, during many days in succession, the bees are able to work at this artificial food. They dwindle rapidly because of this unnecessary and ceaseless labor, just at the time their strength should be conserved to the utmost. The process entails excessive water-carrying at the same time, and unusual excitement generally; hence for my own part I am obliged to condemn this apparently innocent method of supplying that which really is not needed at all by many of the colonies in apiaries where the process is adopted.

The pea flour alluded to is very finely ground and cooked, and is known here as *syming oris*, an article prepared for thickening soups, and of all substitutes is that most sought after by the bees until natural pollen is available.

#### USED IN THE FORM OF PASTE.

I have mixed it with honey as a stiff paste, and then pressed it into the cells, filling about one-fourth of one side of a comb, and placing that side next the outer patch of brood, if any, or within the margin of the cluster if no brood may be started. A brood-nest would

be then developed; but under no possible circumstances will the bees extend the brood area to such dimensions as they do under the genial stimulus of a natural incoming of the pollen of flowers; and this is just where they do not appear to recuperate sufficiently for the trouble and waste of energy incurred. I may suggest that, if mixed with sugar syrup, the paste becomes so hard as to be quite useless.

#### DUSTING FLOUR INTO THE CELLS.

Another method I have many times adopted has been that of shaking the dry flour into the cells from a tin box or can having a number of  $\frac{1}{8}$ -inch holes punched through the lid. A somewhat cleaner plan I have also used has been that of placing about half a pint at a time in a warm dummy feeder having a receptacle that holds only that quantity, and really constructed as a syrup feeder.

#### THE WARM DUMMY FEEDER.

By the way, these small dummy feeders, fitting close at each end to the hive sides, and of the depth of the frames, can be used in cool weather, if necessary; and I may say they are the only kind I have found to overcome the objection bees have to taking syrup from feeders when somewhat cold in the early season. You see, this narrow dummy, being placed close to the cluster, the food always remains at nearly the same temperature as the bee-nest, and is readily appropriate. For the same reason, when filled with artificial pollen the workers crowd into the pollen; and this compact working cluster, with the temperature raised in consequence, is an additional stimulus to collection of the nitrogenous food. While the bee working in the open appears compelled to take wing while padding the pollen in place on its legs, the process is not thus carried out in the dark while the bees remain in the feeder, and the food is carried to the cells forthwith; though in some cases I believe it possible the workers prepare the bee-pap straight from the feeder.

One can, therefore, see how it is possible, for early stimulation, to place one of these warm dummy feeders on each side of the cluster—one with several weeks' supply of pollen, and the other for a periodical fillip of syrup. In this case the spring-fed syrup is used thinner than autumn feed, so the bees are not compelled to carry water. The process may be valuable in some climates, and probably often to the queen-rearer, but it is no use looking at these apparently helpful matters without fully considering

#### THE OTHER SIDE OF THE QUESTION.

Like many other queen-rearers I always have a lot of nuclei to unite in autumn, and the colonies thus established seldom have much stored pollen for early spring use. It is well known that colonies wintered with pollen-stored combs usually breed just a little nearly all the time from the new year onward, in those localities where the weather is not unusually cold, though it may be but one little patch at the heart of the cluster,

and hence this condition is supposed to give such bees a great advantage by the time free flights occur.

The bee keeper finding his colonies absolutely without pollen (though I believe this is a rare occurrence with permanent colonies properly managed) begins to turn things over in his mind, and thinks his bees will be all backward if he does not supply the deficiency. I have done this many a time, and yet often have I declared I would never do it again. But the advent of a backward season, and no natural pollen available, together, perhaps, with a personally restless experimental turn of mind, I have "gone and done it again," hoping that possibly some new adaptation might at last bring the desired result.

In the first place, I would say that a pollen substitute placed in the cells, either dry or in the form of paste, is not all used by the bees, though a great deal is shifted and packed in their cells like natural pollen. When the latter comes in freely there is found the remnant of the stale stuff which the bees do not seem willing to clear out until the genuine honey business is in full swing, and then they have to pare the cells down to the mid-rib before it can be disposed of. There is also considerable waste of the same material corroding the floor, but that is not the end of the subject. It should be understood that, no matter how fine may be the meal given by the owner, whether it be sieved or "dressed" free from all shucks, the bees appear to select only the cream, and a great deal of dross is to be noticed after they have worked it over.

But the real question at issue is whether the substitute is wanted or not. Certainly the bees can not breed without pollen; but if you do not give it to them they will sit still; and bees that are quiet are not ageing or dwindling to any extent, though at the back of my mind I will confess there is some idea that bees wintered absolutely without pollen have not the same stamina as those that have it; for bees certainly consume nitrogenous food in cold weather, if they have it, while they may not be rearing brood.

While the substitute starts them to breeding when fed in early spring, I have always noticed it has not been to the same extent that the natural supply will do, and this is probably why this artificial feeding seems to reduce their vitality ultimately, there not being sufficient compensation for the wear and tear induced.

Certainly I prefer stocks wintered with natural pollen; but when in future I have to carry any through without it I have decided not to give them any substitute, though doubtless I shall shift pollen-stored combs around in due season if any are available.

#### WHITE OF EGG AS A SUBSTITUTE.

Some of your German readers may remember that, many years ago, one of their countrymen claimed to have carried out some very successful experiments (in Germany) by feeding the white of eggs while building up his stocks. I am sorry I have mislaid the paper referring to this matter, so that I can not

now give the exact method. It was probably beaten or whisked into a froth, and mixed with honey. I should imagine sugar syrup would be unsuitable, as the mixture would tend to harden.

#### EXCHANGING COMBS.

So many bee-keepers worry over pollen-clogged combs that, if it were not for the danger from foul brood, a good business might be done in exchanging pollenless for such overcharged combs. The latter would be invaluable to the apiarist who has no pollen in the early season; and if he had to buy such combs they would be cheap at a dollar apiece if in good condition.

Heathfield, Eng., Jan. 24.

[Mr. Simmins in times past has done a large amount of experimental work, and in the matter of giving artificial pollen it would seem as if he had gone over the whole ground. His conclusions, reached from a different set of experiments, are practically the same as those arrived at by A. I. Root many years ago, and, we may say, by all others who have tried giving artificial pollen. In this connection the reader will be interested in our reply to F. Dundass Todd on page 123 of Feb. 15th issue.—ED.]

## HISTORY OF THE INTRODUCTION OF THE HONEY-BEE INTO THE HAWAIIAN ISLANDS.

BY ALBERT WATERHOUSE,  
*of the Garden Island Honey Company.*

[This is the beginning of a series of articles we have in hand on Hawaiian bee-keeping, furnished by prominent writers at the solicitation of the Hawaiian Agricultural Experiment Station.—ED.]

About the time gold was discovered in California a society was organized in Hawaii known as the Royal Hawaiian Agricultural Society. At a meeting of this society held in Honolulu on the 14th of August, 1851, the following resolution was passed: "Resolved, That a committee be appointed to procure the honey-bee from Australia, Central America, or Chile, who are authorized to incur the necessary expense. R. C. Janion, chairman, Baron de Thierry, J. Montgomery, were appointed."

As California was still only a mining camp, no bees were to be found there, and the first efforts of the committee were to secure colonies from New Zealand. At the annual meeting of the society in June, 1852, the committee reported a promise of three colonies from New Zealand. I quote the following tribute to the honey bee from the committee's report, written by Baron de Thierry:

The bee, from sipping the sweets of the flowers, takes nothing from their beauty; and if we should benefit the neighbor who has bees whilst we have none, we know that, even in so small a degree, we are contributing to the welfare of our fellow-creatures. The cultivation of flowers promotes domestic happiness, soothes the mind, and richly repays for the trouble bestowed upon them. The wealthiest, accustomed to the glare and glitter of state, are prouder of a fine nosegay than of their massive plate and costly silks; and the mightiest of queens would scarce appear in festive attire without a bouquet in her hand or a rose in her bosom, emblematic of the purity of her mind and homage to the exquisite works of a greater Being above.

But whilst the palace and the cottage, the dwelling of the richest and the poorest, are so eminently improved by these most attractive of nature's vegetable works, the indefatigable bee collects tribute from every flower, and hordes its treasure with equal fidelity for the cotter as for the magnate, adding to the comfort and profit of both by its unceasing industry. The little stranger, perhaps at this moment on her way, will be the means of visiting upon you an important and inexpensive article of export; and in return for such service, and for the additional comfort which families will derive from that healthful article of diet, and the wax which she so abundantly produces, I trust that some exertions will be made to raise flowers for her support.

Although the promise of bees from New Zealand was made, it was never fulfilled. The same year, 1851, the first actual attempt to bring the honey bee to Hawaii was made. A colony was forwarded by sailing vessel from Boston. The details are given in the following report by C. R. Bishop, read at the June meeting of the Royal Hawaiian Agricultural Society in Honolulu, May 26, 1854.

W. CHAMBERLAIN, *Chairman of the Committee on the Honey-bee*—

Dear Sir:—Being one of your committee, and having had within the last year a little experience with the unfortunate colony of these interesting insects upon which you are expected to report, I will give you what information I can relating thereto. I believe that each year since the formation of the Royal Hawaiian Agricultural Society, except the present, there has been offered a premium for the introduction of the honey-bee into these islands. The only persons that I know of who have really been at any expense and trouble to accomplish so desirable an object are Henry A. Pierce, Esq., of Boston, a life member of the society from its foundation, and contributor to its objects in various ways, and Capt. Stearns of the bark Matanzas. In 1851 Mr. Pierce put on board the ship R. B. Forbes one swarm of bees and offered the mate a liberal reward if he would take care of and deliver any of them safely. The hot weather in the South Atlantic melted the honey and drowned all the bees in the hive. In February, 1853, he procured another fine swarm, well stocked with honey, and was at a large expense, some \$140, in having it secured on the deck of the bark Matanzas in such a manner that seemed to insure its safe arrival here. The hive was placed in a strong box, leaving a space of six inches all around for air between the hive and the box; then a packing of ice two feet thick above, below, and on each side; outside of which was a space of six inches filled with charcoal, and all enclosed in a case 8 feet square having two lead pipes 3 inches in diameter running from the outside to the hive to supply the bees with air. Capt. Stearns also purchased a swarm and placed the hive inside a box having wire cloth nailed across openings in the sides, and hung at the end of the boat just forward of the cabin. The bark had a long passage, 150 days, and, being becalmed a number of days in the vicinity of the equator in the Atlantic, a part of the ice melted, and during the rough weather off Cape Horn thumped against the decks so heavily as to jar many of the bees down into the water. After they doubled the Cape, Capt. Stearns had them taken out of the large case and hung up under the boat with the other swarm, where they both appeared to be doing well until they arrived within about ten days of this port, when moths made their appearance in the boxes, and the bees commenced to die rapidly, Capt. Stearns' more than the other. When the bark arrived off Honolulu in August, 1852, I went on board, examined Capt. Stearns' hive, and found large numbers of moths, worms, larvæ, and some dead bees inside, but no live bees. The other hive was in very bad condition, containing swarms of moths, worms, and larvæ among the honey-comb. A few bees were living, and they had plenty of honey, some 15 to 20 pounds, a part of which, in the chamber of the hive, was very handsome. I took the hive to my garden, where, with the kind assistance of Capt. Stearns and others, we removed as many as possible of the moths and cleared the hive of worms, dirt, etc., as well as we could, and afterward removed nearly all the honey. There appeared to be from 40 to 60 bees living, among them the queen. The hive of bees and honey was put up and sold at auction in order to give persons understanding the management of bees, or wishing to have them, an opportunity to purchase. I purchased them, had a new hive made, and tried to induce them to occupy it, without success. After a few

days I thought they seemed to be less active than usual, and upon examination found but three or four bees remaining, and, a day or two after, none at all. As there were no dead bees in the hive or on the boards underneath, and no birds about to destroy them, I concluded that they had found some place more to their fancy than the hive, and that I should again see them or hear of them; but I have not, and am unable to account for their disappearance or fate. Capt. Stearns took excellent care of the bees; and had he had a short passage, or even a passage of from 130 to 140 days, would have delivered both swarms in good order which proves that they can be brought from the United States via Cape Horn without any great expense or trouble except to have them secure against any excessive heat and rough handling; but great care should be taken in the beginning to select hives free from moths and their eggs. Had the swarm mentioned arrived here in better condition it probably would have been better to send it immediately to a cool locality on Maui or Kauai in the vicinity of sugar-plantations and banana-fields; but it was too far gone to admit of any delay in removing the destructive enemies of the bees.

We have a great variety of moths and ants in the islands, from which it would require constant care to protect the bees. I have lately learned that honey-bees have been recently introduced into California. By and by we shall probably be able to get them from there more easily than from any other place. The thanks of the society are due to Capt. Stearns and Mr. Pierce, who, in my opinion, should be partly or entirely remunerated for the expenses incurred in trying to supply us with so interesting and useful an addition as the honey-bee. CHARLES R. BISHOP.

After these failures no further attempts were made to bring the honey-bee to the Hawaiian Islands until after colonies had been successfully established in California. On the 21st of October, 1857, Capt. Lawton, of the ship Fanny Major, landed four hives of bees that had been shipped from San Jose, California. These four colonies, according to Dr. W. D. Alexander, were placed in Dr. Hillebrand's garden in Honolulu, and are reported to have thrived well. Two of these colonies were afterward purchased by the Royal Hawaiian Agricultural Society for \$100 apiece, and the other two colonies were purchased by private parties. These four colonies were the first honey-bees to become established in the Hawaiian Islands, and from them have descended many of the wild swarms to be found in the trees and cliffs of the mountainward regions of the islands.

### CUT COMB HONEY.

Should it be Sold for a Low Price? Liquefying Honey by Solar Heat.

BY F. GREINER.

In the foreign bee-journals it has been no uncommon thing to see comb honey advertised "in tin boxes (Blech-Dosen), so many kilos for so many marks." These advertisements imply that the comb is being cut out of frames, and packed into the tin receptacles (flat boxes). We had been accustomed to look with contempt upon such a slovenly way of marketing comb honey. I flattered myself that we in America were marching at the head of the procession, and that "cutting" comb honey to be marketed was not to be thought of.

From what the editor says on pages 765—767, Dec. 15, it appears that we are falling in line with the brethren across the water, and

the method which we have been inclined to treat with contempt may soon be the popular one. If it is possible and practical, and meeting with favor among the consuming classes, to put up quarter-pound packages of comb honey in paper cartons it will be so with full-pound parcels. Eventually we may put up fifty-cent or even dollar lots in these paper boxes lined with paraffine paper.

Comb honey produced for this purpose is, of course, most probably raised with shallow supers without separators, or in regular extracting-supers, frames either being filled with very light comb foundation or not, at the bee-keeper's option.

As the editor says, we shall sooner or later be compelled to give up the use of sections on account of the scarcity of suitable timber to make them. If we are prepared for this emergency we shall be the better off. In time of peace is a good time to prepare for war. Paper may help us out. Paper for the honey-containers, paper for shipping-crates! The greatest advantage, however, will be found in providing a super which is most congenial to the bees, one which they will not hesitate to fill. We shall be able to produce very much more honey with the inexpensive outfit, cheapening the product on both ends. There will be honey and money galore for the bee-keeper in the future unless he sees fit to divide the spoils with the consumer.

So far it does not look like cheapening the product to the consumer. Twenty-five cents for  $\frac{1}{4}$  pound, or about four times as much per pound as the section honey is sold for in the large cities late years—that is the price named by the editor. I pity the poor consumer, or would-be consumer, of comb honey. May we expect to dispose of our comb honey at such a fabulous price? I do not think so. I think we must even cut the now established price by a good deal if we dare expect to sell such large crops of honey as we shall then produce. At the present price of 15 cents per one-pound section here in the country the sale is limited, and the largest portion of my yearly output has to go to the city. At ten cents per pound I might expect to sell a large portion in my home market. Lower-priced honey is the demand here, although it seems, since labor is paid so much more than formerly, that we as honey-producers ought to be paid better also by receiving better prices.

If cheap honey is demanded, why don't the honey-eating people buy extracted honey? might be asked. The answer is, because by far the larger majority of them do not want extracted honey even at half price. They prefer the most inferior comb honey, such as that from unfinished sections, dark honeys, even honey-dew-flavored honey, to the finest extracted. I do not understand why this is so. I have many times been shocked by hearing the above sentiments from people who, I had every reason to think, had been converted to the extracted honey. Others who had bought my best extracted for years, ceased to be customers for it when

they found that inferior comb honey could be had at about the same price. This state of affairs has been and is very discouraging to me, and there is no wonder that I have been inclined to give the Texas bulk-comb-honey production a trial.

I have hesitated on account of liquid honey granulating here in this climate so readily. I could not believe that people were willing to dig into a sixty-pound-can of solidified honey after the comb.

#### LIQUEFYING HONEY BY THE HEAT FROM THE SUN.

Mr. Boardman's sterilizing method, see pages 769, 770, 1909, might give some relief. He can undoubtedly tell how long extracted honey must be exposed to the direct rays of the sun to prevent its granulation afterward. As was reported some years ago in GLEANINGS, we have liquefied honey in a solar. When it was assured by Selser and others that bottling honey hot would prevent granulation, we heated honey in half-pound tumblers in our solar and sealed it. We observed no difference between honeys heated on the stove and such as is warmed in the solar; but we did not leave honey in the solar long at any time.

The objection made to the solar machine was that the sun could not be relied upon at all times, and that artificial heat was, therefore, better, particularly so in the fall of the year when granulation occurs. This is true, and for this reason I have used my solar but little of late. When I attempted to liquefy three-pound cans full of hard honey, and I failed to shift the apparatus around with the sun at the end of the day, I found portions in each can still hard, and then I had to leave the cans of honey for another day. The next day, as luck would have it, it would be cloudy or partially so. There were times when the honey in these 3-lb. cans did not warm up in a week. This was disgusting. To liquefy honey in 60 lb. tin cans in this way is out of the question. If I were to build a large solar machine for heating honey I would use artificial heat in connection with the solar.

If found necessary to keep extracted honey in the sunlight for a long time, one will have to build a regular glass storage house and put up the whole crop in glass. This latter is not a very bad practice for one who has a demand for his honey in glass packages. I know of some who follow this plan. They need less tank room, for they draw the honey into their retail packages soon after extracting. When granulated the cans are treated to a hot-water bath, and the honey is thus speedily liquefied. After thus being treated it does not again harden for quite a while. This method may be less expensive than the Boardman sterilizing process. The great advantage a solar machine has is that honey is never overheated. This can not be said of the other plan.

This subject of sterilizing honey is a very interesting one, and many of us want more light on it. We should also like to know why honey granulates sooner when often handled. If a chemical change has been effected

by sterilizing in the Boardman way, is it possible that this change may be nullified by turning the bottle of honey over and standing it on the other end?

Naples, N. Y., Dec. 26.

[Our correspondent expresses pity for the consumer who has to pay 25 cts. for  $\frac{1}{4}$  lb. of honey. While we share to a certain extent this feeling, yet when we come to consider the cost of the package cutting up the honey into small squares, of taking care of the drip, and the further fact that the railroad companies must have a reasonable profit, 25 cts. is not out of the way; and we must not lose sight of the fact that comb honey put up in this way is a choice tidbit, and so far from being a staple it is a luxury. It is fully the equal of other choice desserts found in the Pullman diners.

Why not go out on a campaign, as the makers of cheap syrups do, and get something nearer the value of our honey in comparison with some of the stuff that ought never to go into the human stomach? If we bee-keepers encourage low prices and sell at low prices, there is danger that our product will go down to the level of table syrups when in fact it should go higher.

When  $\frac{1}{4}$  lb. of comb honey is sold for 25 cts we must take into consideration that it costs money to get these small portions before the trade, and that it must be of the very finest quality. Any thing but the very best would ruin the trade instant. Travelers on Pullman cars, and patrons of high-class restaurants, do not care so much for the cost of an article provided it is of first quality. They are willing to pay the price for they have the money, and in our opinion it is not necessary to waste any pity on them.

It has been demonstrated that honey can be sold at a fair price providing the right kind of educative advertising is used. We must dissipate the notion that comb honey is manufactured, first of all. We must show that the flavors of honey vary as do the fruits from the orchard. We must show that our product is more easily digested than any other sweet known, and that, while it costs more, it is worth more. Why, then, be content to get a paltry 10 or 15 cts. per lb. for an article that is intrinsically worth 20 or 25 cts. as compared with other sweets.

Admitting that there is a demand for a low-priced honey, let us supply that trade with candied honey in paper bags, or extracted in tin buckets or paper pails. In this campaign of advertising we should show that extracted is just as good as comb honey. We must first of all convince the consumer that it is not glucose, but much better than glucose or any of the cane syrups.

Bulk comb honey can be sold in the Northern States; but retailers must be cautioned to keep such goods at a temperature not lower than 70 degrees Fahrenheit. A great many groceries have a temperature of about 70 during the day, while at night it goes down to nearly freezing, and Sundays it goes even below that. Bulk comb honey can not be

sold in such stores. It is doubtful if any sort except that which is candied could be sold in such places. This is one serious objection to chunk honey in the North.—Ed.]

---

## NATIONAL BEE-KEEPERS' ASSOCIATION NEWS ITEMS.

The Wisconsin State Bee-keepers' Association was first to join the National in a body, and has ever since continued in that relation. It was also the first this year to vote to send a delegate to the National convention of 1910. Let other State and local associations do likewise, and thus build up both. The membership of the National to-day, Feb. 19, is 3600.

The Executive Board asks all to report to President York or the General Manager any suggestions as to how the National Association can be of more help to its members. Several suggestions have been received already, but others are wanted.

The revised edition of "Bee-keepers' Legal Rights" is now in the hands of the printer. A copy will be mailed free to any member requesting it.

There have been two more recent cases of bee-keepers sending in their dues and asking for help after getting into trouble. This is contrary to the constitution. No insurance company insures burning houses.

The poison-spraying of open fruit bloom in the Southern States has begun, and some apiaries are already affected by it. Complaints of bees spotting the washings hanging on lines in the South are coming in. The North will have similar complaints later. The long cold winter is likely to cause much spotting of washings when bees have their first flights. The bee-keepers should try to plan the wash-days and place their bees out afterward.

It has been suggested that the time and place of the bee-keepers' conventions throughout the country be arranged with the Executive Board of the National Association. If this is done, it may be that dates can be selected when certain officers of the National can be present at nearly all local meetings; and it may be that the system of meetings for the good of all can be planned, something like the various State fairs in the fall.

Director R. A. Morgan, of South Dakota, suggests that the National issue quarterly instead of annually, and save postage; also, the more frequent reports will help to create more interest among bee-keepers.

Director J. E. Crane, of Vermont, thinks it would be a good thing if the National would own and rent to members stereopticon views for bee-lectures, and thus better advertise the use of honey, and also have the National advertise in papers.

Thomas Chantry, of Utah, suggests that the dues of the National be increased so that there will be more money in the treasury for use in the interest of membership, and he would urge every present member to get in new members for the National.

Up to this date, Feb. 19, since the last National report was issued, the General Manager has received \$1.00 from each of 80 members, and 50 cents from each of 545 members. This far exceeds any other year for fifty-cent dues, and shows that the local associations are co-operating very nicely. The fifty-cent rate to local associations when joining in a body helps the National, both in number of members and financially.

Invitations for the 1910 meeting of the National have been received from Toronto, Can.; Buffalo, Albany, and Rochester, N. Y.; Nashville, Tenn., and Zanesville, Ohio.

The Executive Committee will not decide as to the time and place of the next meeting until, perhaps, the first of June, so there will be plenty of time for other cities to get in their invitations to the General Manager before the final decision is made.

There ought not to be very much trouble in getting the desired 5000 membership by the time of the National convention of 1910. There are now 3600 members, so that only 1400 more would be necessary.

Those who are in arrears in their membership dues are kindly urged not only to remit at once to the General Manager, but also, if possible, to get their neighbor bee-keeper to become a member also. In this way the 5000 membership could be gotten within the next sixty days. Why not do it?

N. E. FRANCE, General Manager, Platteville, Wis.

MRS. J. W. BACON'S APIARY OF LARGE HIVES FROM WHICH THERE WERE ONLY FIVE SWARMS LAST YEAR.

### SHORT CUTS IN A QUEEN-REARING YARD.

#### Putting Bees and Queen into a Mailing-cage to Avoid Stings.

BY MRS. J. W. BACON.

I see you have trouble by getting stung when putting up queens to mail. I have worked at this for a number of years, and in putting up hundreds of queens this year I had my thumb stung just once. Try it this way:

Fill the candy-hole, and tack the wire cloth on all except the last hole at the end. Now turn the wire cloth back, not quite half way, and you will have a long narrow space to put your bees in. Hold the cage in the left hand, with the thumb over the opening. Catch the queen first, and the bees by the wings as they have their heads in cells of honey. If you hold the cage so the back end is up they will run into the middle space.

I wear an apron made of factory cloth, with a double pocket — i. e., a small pocket on the outside of a large one. The small pocket is for tacks and the large one holds my hive-tool, leadpencil, a small wing to brush bees with, and a dozen queen-cages.

When catching queens I take along a box with blocks of eggs; and if I find a hive without eggs I do not look for a queen, but give them a block of eggs. I can give out eggs and catch a dozen queens in less than an hour. The next time over, or in two or three days, I find queens laying in many hives to which I gave eggs; and if they have started cells I give them a virgin queen; and so it goes, a continual round for the season.

I use lard on my hands to keep the propo-

lis from sticking; and if the bees are cross a little honey on the back of my hands seems to quiet them.

#### THE ADVANTAGE OF A LARGE HIVE.

I see that large and small hives are discussed. Ours are about right. They have a tight division-board and chaff cushion on each side. We winter our bees on eight frames. One can easily make this hive large (fourteen frames) or small, in the spring. The strong colonies are soon ready for an extra frame, and sometimes we keep putting in frames until they have twelve. When we are ready to put supers on these hives we take out these extra frames of brood, shaking off the bees, and use them to strengthen weak colonies, thus reducing down to eight frames. The bees fill the supers immediately. You see I would not want a hive that could not be made large or small at will. Taking out the brood at this time seems to retard swarming. We had five swarms from sixty colonies last year.

Waterloo, N. Y.

[The plan you describe for putting bees in a mailing-cage is all right. We used to employ that method; but it took so much time that we abandoned it in favor of the plan that we described and illustrated. Our boys seem to prefer the faster plan, even if it does result in more stings to their fingers.]

If a colony be given a large amount of breeding capacity, such as can be afforded by a large hive there will be far less swarming than from one where the breeding room is limited. The bee-keeping world has not given this question enough thought and attention. Our columns are open to a further discussion of the matter.—ED.]

SYVERUD'S AUTOMATIC BEE-BRUSH.

As the comb is passed between the brushes they revolve in the opposite direction, thus wiping the bees from both sides at once.

### AN AUTOMATIC BEE-BRUSH.

#### A Double Brush for Freeing Combs of Bees Almost Instantly.

BY L. A. SYVERUD.

In shaking bees from combs I have often thought how nice it would be if we could get the bees off quickly without scattering them too much. With this in mind I constructed a brushing-machine as shown in the accompanying illustrations. The device is what I call a rotary bee-brush, and it wipes the bees from both sides of a comb at one operation as rapidly as the comb can be handled.

In the first view the position of the comb is seen when it is ready to be passed between the brushes, the right hand just touching the cord, which, when carried out by the hand, revolves the brushes in the opposite direction from that in which the comb is moving, and instantly cleans it of bees, that is, the same movement that pushes the comb between the brushes pulls the cord which causes the brushes to revolve.

I like to have the bees drop at the entrance of their own hive; and to do this I have arranged a hopper in front of the brushes (not shown in the picture), to prevent the bees from being scattered too much. I place the machine in front of the hive and a little to one side, so that the hopper is directly in front of the entrance. I remove one comb at a time, give it a shake into the hopper and pass it quickly between the brushes; then swing it around to the back of the hive and put it directly into the comb box or bucket. The work can be done in much less time than by ordinary methods. Coiled

wire springs revolve the brushes back to their original position, and also wind up the cord ready for the next comb. Next season I expect to try foot power for operating the brushes.

Canton, S. D.

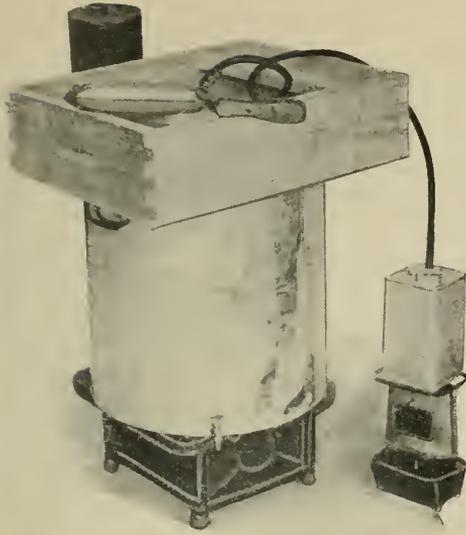

[Double brushes, for brushing *both* sides of combs at once, have been illustrated in these columns before; but Mr. Syverud has gone one better by making a revolving brush, the bristles revolving *against* the side of the comb. At first thought this seems like a good principle. It is a question, however, whether a machine like this can be carried around to each hive and adjusted to the inequalities of the ground, and in the end save time over a common hand brush. The roller brushes would need washing, probably, as often as any brush. —ED.]

### NEW INVENTIONS FOR EXTRACTED-HONEY PRODUCTION.

#### Some of the New Appliances Tested.

BY H. H. ROOT.

In the November issue of the *Bee-keepers' Review* Mr. W. Z. Hutchinson gives his experience with uncapping-machines, capping-melters, honey-knives, etc. After having tried the Ferguson uncapping-machine, described on p. 403, July 1, GLEANINGS his verdict is that, if combs are built with plain  $\frac{7}{8}$ -inch end-bars, and are as straight and smooth as a board, and slightly bulged on each side, so that all of the capping surface projects about  $\frac{1}{4}$  inch beyond the edges of the end-bars, but little more can be asked for in the

Steam uncapping-knife.—A gallon can over a double flat-wick oil-stove furnishes the steam necessary.

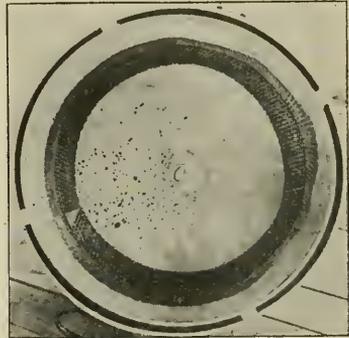

way of an uncapping-machine. However, although all of his combs are built on wired foundation, not one in four, he says, answers to the above requirements. Even when a comb is reasonably straight, he points out that one side is often slightly bulged while the other is correspondingly depressed, the result being that one side is uncapped perfectly while the other is untouched.

In our own extracting we also have given the Ferguson uncapping-machine a trial, and we agree perfectly with Mr. Hutchinson. We have not tried all of the uncapping-machines that have been described and illustrated; but in our opinion there are a few objections that will hold true with all. We believe that the mere cutting of the cappings and getting rid of them is only a part of the problem that presents itself. The real problem is to *uncap the depressed surfaces without complicated mechanism, the expense of which is prohibitory.* We are sure that an uncapping-machine may be built, and probably is built, which will uncap in a satisfactory man-

ner; but the question is, are such machines practicable? For the majority of combs, even should the machine do the work, it is probable that individual attention would need to be given to take care of the depressions, and we very much doubt whether much faster work could be done, in view of this, than a skilled operator can do with a good uncapping knife.

THE STEAM-HEATED UNCAPPING KNIFE.\*

For several years we have believed that the steam-heated knife is the best solution of the uncapping problem; but we have hesitated to say very much about it for fear that there might be some objection to it that would come up after the plan had been tried extensively. Mr. Hutchinson calls the steam-knife a "daisy," and regards it as one of the "biggest little inventions of the apicultural times." The best thing about the steam-knife is that it does not get clogged or gummed up, and we have found that a razor edge is not as necessary as with a cold knife. A cold knife that is good and sharp works well until wax begins to adhere to the edge, and then the knife mutilates and tears the comb in a most aggravating way. This trouble

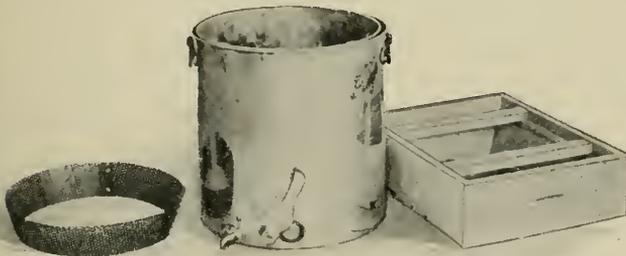

The inside of the capping-melter looking from above, showing the circular screen at the bottom.

may be overcome by dipping the knife in hot water, but this is only a partial remedy. The steam heated knife quickly passes through tough or tender combs with ease, and without breaking or mutilating the cells.

Much less force is needed, and the work is not nearly as tiresome.

A tea-kettle with the rubber tube attached to the snout by means of adhesive tape may be used for a boiler; but a copper can is better. If the tea-kettle is used, several thicknesses of cloth

The Root capping-melter showing the removable circular screen. The square box is placed over the top of the can, and give plenty of room for the operator.

\*This device (or one quite similar) was first used in Europe. It appears to have been illustrated and described in several European bee-journals some years ago. We first showed it at the National Detroit Convention in 1908, although we had been using it a year prior to that time.

BEES KEPT IN A HEN-HOUSE WITH HOLES SAWED FOR THE HIVE-ENTRANCES.

should be placed over the opening, and the lid crowded down tightly to make a snug fit. A round disc of pasteboard inside the screw-cap on a can makes every thing steam-tight when the cap is turned down with the fingers.

#### THE CAPPING-MELTERS.

Mr. Hutchinson found that the large Beuhne capping-melter did satisfactory work when he removed the inner separator and allowed the honey and wax to run out away from the heat as quickly as possible. Whenever the inner separator was used, the honey was spoiled because of the long continued heat; but when the honey was gotten away from the heat immediately, the flavor and color were not injured. Mr. Hutchinson did not find the Root capping-melter satisfactory, for the reason that it did not have enough capacity for the rate at which he was extracting. The one-burner Root-melter, as has been described in these columns, is not intended for the largest apiaries, where from two to five thousand pounds of honey is extracted per day. At this rate a larger melter must be used, and there must be two burners to furnish enough heating surface to get rid of the cappings as fast as they are removed from the combs. An improved strainer is now used on the Root melter, which greatly increases its capacity, but, at the same time, a much larger size is needed for the largest apiaries.

There is one point that ought to be mentioned in connection with capping-melters; and that is, that, if the honey and wax are not separated while hot in some such arrangement as the Aikin separator, which has been described before, the honey, if allowed

to cool under the layer of wax on top, takes on, in some way or other, a waxy flavor which is not noticeable if the wax cools by itself. We can not explain this; but we believe it to be a fact, since others besides ourselves have noticed it. For the best results, therefore, a separator should be used.

---

### BEES AND CHICKENS IN THE SAME BUILDING.

BY W. T. BAILEY.

I started in the bee business with four colonies in the fall of 1908. Not knowing any thing about it I put the hives in the hen-house and sawed holes for the old-fashioned entrances to stick through.

I was so much interested in bee culture that I talked bees to every one I met, and one gentleman loaned me a very old and well-worn copy of a bee-book which proved to be the A B C of Bee Culture, by A. I. Root. This book made me a winner, and I have since felt very friendly to bee people, and especially to Mr. Root, and my gratitude goes out to him. From the four old colonies and two new ones last summer I secured about 150 lbs of comb honey, which was sold at a good price. I now have ten colonies; am Italianizing, and expect to glut the market next year.

Suffolk, Va., has 10,000 people, two miles west of the Great Dismal Swamp, and is the biggest peanut center in the world.

## THE MOTOR CYCLE FOR THE BEE-KEEPER.

Traveling to Outyards at the Rate of a Mile a Minute.

BY L. F. HOWDEN.

Having had three years' experience with motor cycles I am glad to relate my experience, as it may be of some benefit to those who run out-apiaries—particularly those who need some means of locomotion that is more rapid than the horse or even the automobile.

Of course, there is much pleasure to be derived from riding a motor cycle; but notwithstanding this fact I used mine mostly for business, having found it to be a wonderful money-saver by saving time, which is quite an important factor with a man who runs out-apiaries many miles from home.

Another reason why the motor cycle excels other means of travel is its low expense of up-keep. I have found that, after riding a two cylinder five horse-power "Indian" 4000 miles, my expense for repairs has been only \$10.00 to 15 00, which is surely a small amount when one takes into consideration the distance traveled, time saved, and the satisfaction of having this willing steed always ready. The oil and gasoline required to run a motor cycle depend on the condition of roads, hills encountered, etc.; but I think that, as an average, a gallon and a half will run one a hundred miles.

The speed of a motor cycle is almost un-

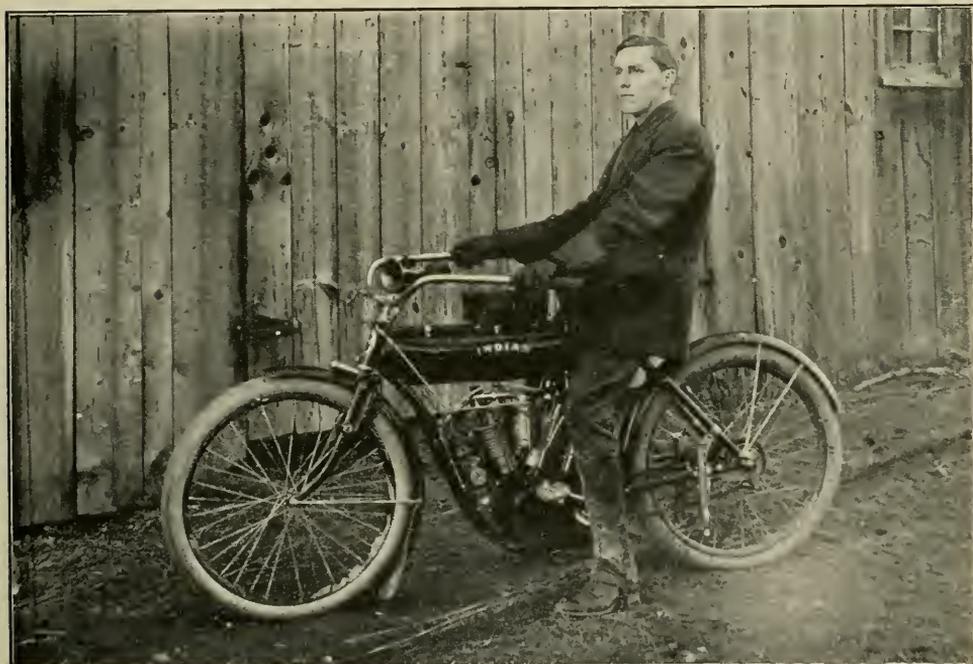

limited. I have traveled at the rate of a mile in fifty-five seconds, and there still seemed to be more speed in the machine. It is rather hard to tell what the maximum speed might be; but I think this rate is fast enough for the ordinary bee-keeper. It is also possible to throttle the machine down to five miles an hour.

As I have been in the supply business I had my machine equipped with a luggage-carrier which I used to quite an extent for carrying packages to and from the depot, having carried as much as 50 lbs. at once.

To those who ask how the "Indian" climbs hills, I will say that the five-horse power machine will climb any hill that an automobile or horse and wagon will negotiate. Those who live in a hilly country should buy the two cylinder five-horse-power model selling for \$275.

Fillmore, N. Y.

[There are several good makes of motor cycles on the market. Besides the one mentioned in the article there are the following: Curtiss Reading Standard, Thor, Yale, Merkle, Pierce, and some others. The self-propelled cycle has now come to so high a state of perfection that it can no longer be considered an experiment but a practical everyday machine for business or pleasure. The expense, as stated by our correspondent, is very moderate. Something, however, will depend on the mechanical ability of the rider and his care of the machine. If he fails to keep his bearings well adjusted and oiled, and allows his machine to get out of

LEON F. HOWDEN READY FOR A LIGHTNING TRIP TO AN OUT-APIARY.

A. I. ROOT'S FLORIDA HOME, WITH A GLIMPSE OF THE TROPICAL VEGETATION ON THE NEW ACRE JUST PURCHASED FOR THE CHICKENS.

order, he may have some expensive repairs. If the directions of the salesman are carefully followed out, there is no excuse whatever for any unnecessary wear on the machine. The chief expense for up-keep will be for tires; and the cost even then will depend very much on the speed with which the rider drives, and whether he is careful to pick his way, selecting the best parts of the road instead of taking every thing as it comes—glass bottles, sharp stones, and all.

In this connection we would not advise any driver of a motor cycle to go faster than 25 miles an hour. This is fast enough. High speeds increase the cost of up-keep, to say nothing of the danger. While some of the high priced machines are capable of making a mile a minute, there is considerable danger at such speed. One young man in our locality, a fast rider, took a severe tumble, and was unconscious for several hours. It is a wonder that it did not kill him.

As between a double cylinder and a single-cylinder machine, the latter will take practically all the hills unless the grades are very steep. The two and four cylinder machines are a little quieter in operation, while the single cylinder gives off a sharp bark at every impulse. In localities unrequented by automobiles some horses are badly frightened by the single cylinder exhaust.

It is our judgment that a good motor cycle can be very advantageously used for out-apary work. The cost is insignificant when compared with an automobile; and when one does not wish to carry too large an amount of luggage he can make a trip to the

yards quite as satisfactorily as in a full-fledged auto.

Perhaps the average person feels that he could not learn to run an autobike. Almost any one who can run a common bicycle will have very little difficulty in learning to handle one of the self-propelled type. He should seek, however, to get all the "pointers" possible from the agency where he gets the machine. Then if he will be content to ride at a moderate speed and every day look over his tires, bolts, and nuts, and see that his machine is well oiled, he will have very little trouble.

Very good second hand autocycles are sometimes to be had at one-half or two-thirds the price of a new machine; ordinarily, however, we would advise the purchase of a new machine; and for out apary work we would get a luggage-carrier in connection. The price of the single-cylinder machines runs up to about \$200.—Ed.]

#### THE MOTOR CYCLE FOR CARRYING SUPPLIES.

BY H. G. QUIRIN.

We note that we are to have several articles on the automobile and its use in out-apary work. We are all interest, as for some seasons past we had been thinking of getting one for that very purpose, but for various reasons did not do so. Instead we bought an up-to-date motorcycle, for we figured that we could build a carrier on the rear, which

would enable us to carry 50 to 100 pounds. This, together with a horse and spring wagon we have, answers all right except in the fall when the bulk of the honey is taken off, when, of course, we require a two-horse wagon.

While the motor cycle fills the simple want of taking one over the road, it is not all that one might desire when it comes to carrying freight. In the first place, it has no springs and does not ride as easy; and in carrying bees and foundation it takes careful riding over the rough spots so as not to knock out the foundation and smash the combs; but by placing a thick cushion on the carrier, and wedging up the frames of foundation good and tight, one can carry them all right. When carrying bees and brood it is necessary to have the frames wired, and such combs selected as contain but little or no honey. Of course, old and tough combs which are well fastened at all sides are preferable to new ones at all times.

When it comes to speed, there is nothing to compare with the motor cycle, as most standard makes speed up to a mile a minute; but for rough, sandy, or muddy roads, they are no good.

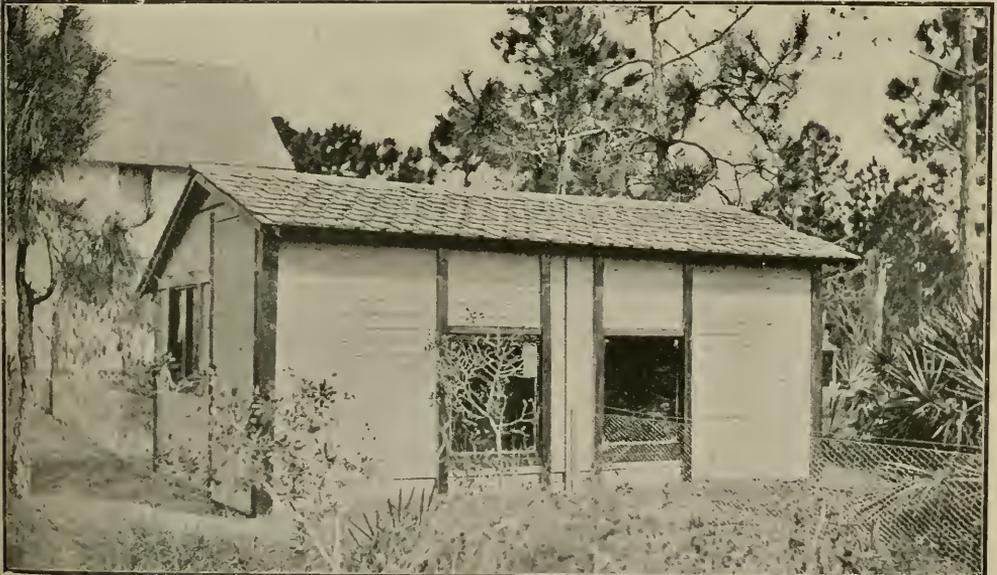

It seems to me that the ideal auto for a bee-keeper would be of the high-wheeled type with friction drive, solid tires, and built after the fashion of a spring wagon, motor to be air-cooled, and the rig capable of carrying about 500 to 800 pounds. There is a high-wheeled auto delivery in our town, which does an express business and has been running all winter through all this snow. I think it is an International.

Bellevue, Ohio.

### A. I. ROOT'S FLORIDA BROODER-HOUSE.

Through the kindness of one of the readers of GLEANINGS from the North, who visited us with his *kojak*, I give you a glimpse of the brooder house I have mentioned, and also a view of our Florida home with some of the trop cal vegetation in the foreground. The brooder-house is 8×14 feet, an divided by netting in the middle so as to make two rooms, 7×8 feet each 4½ feet high on the north side, and 5½ high in front. Wesley and I built it, although neither of us is a carpenter. Almost every stick of material is cull flooring that costs here only \$12.00 per 1000.

The sills are 2×4, but all above the sills is this flooring 4 in. wide. The corner boards are flooring nailed together, and the siding is then nailed *inside* of these. I ordered cheap shingles; but as they were out, I took the best cypress and placed them two inches apart, as you will notice in the picture. I got two damaged windows to let the sun in on cool mornings. Each apartment contains a brooder with 25 chicks, and by shutting the doors as soon as it begins to get chilly at night you would be surprised to see how warm and comfortable it is inside until the sun gets up again next morning. On the north side are long shutters 2 ft. wide, that can be swung up under the eaves during very warm weather. The netting that goes down a foot into the ground keeps out all night prowlers; the joints are all tight enough to keep out cold winds and frost, if any should come, and the chicks have a dry warm place to scratch and exercise when it is damp or

THE BROODER-HOUSE THAT KEEPS OUT THE "VARMINTS," LETS IN THE SUNLIGHT, AND TEACHES THE CHICKS TO "GO IN WHEN IT RAINS."

rainy outside. Clear around under the eaves is a little long box or shelf where all tools and small things needed in the care of the chicks may be kept out of the way, where they can be seen at a glance, and where you can reach them without any stooping. My decision is, just now, that if you are going to run an incubator (even down in *Florida*) you need some sort of brooder-house. I do not think this one cost labor and all, over \$40 00. Several who have looked it over have suggested it wouldn't be a bad place for *two people* to live in, in this genial climate, especially if the aforesaid "two people" had got tired of paying out money for rent, and, at the end of the year, having nothing to show for it. I might add that Wesley and I have built three similar houses for roosting and laying houses. These, however, have no windows nor doors except screen doors covered with netting. The whole south side is netting. Each house is shut up at night and opened at daylight.—A. I. R.

### FASTENING FULL SHEETS OF FOUNDATION IN SHALLOW EXTRACTING FRAMES.

#### The Spoon and Melted-wax Plan Found the Most Satisfactory.

BY F. DUNDAS TODD.

In the shallow extracting-frames I use full sheets of foundation; but neither in those of my own make nor in those made by Root is there provided a wedge device for fastening in the sheets, so one must fall back upon wax as a cementing medium, or grip between two strips of wood. My preference is for wax.

When brought face to face with the problem of foundation-fastening I gathered together the literature upon the subject in the various magazines and books and compared them all. Mr. Hutchinson described one method that looked rather alluring—one in which a mixture of beeswax and resin is melted in an oil-can and poured from the spout on to the top-bar of the frame alongside the edge of the sheet. I will admit that, in Mr. Hutchinson's hands, the scheme probably worked first rate; but with me it was an utter failure. I tried two different sizes of cans, and experimented with various sizes of aperture; but the wax set in the nozzle on the first pouring, and then the fun began. For a while I tried boring out the hole each time with a nail, but soon the clogging worked its way downward beyond reach. Then I tried plunging the can into the hot-water bath with the nozzle down. This melted the wax all right, but soon there was more water inside than wax, while outside the wax was speedily getting on top of the water. Besides, I was burning my fingers, and while it is possible my digits may in due season become inured to bee-stings I am afraid they will never become immune to scalds from hot water. So the Hutchinson idea after a

fair trial was voted unsuited to this locality. Louis Scholl's spoon method looked sloppy and inherently lacking in nicety; but I have a high opinion of his opinions, so I decided to give it a trial. After a little practice, and getting the tools adjusted to suit my hand, I found the system exceedingly good, and now I can fasten a few hundred sheets of foundation into position in a little while.

The essential tools are a suitable spoon and a frame-rack. "Suitable" is a rather vague term; but I have tried tea, dessert, soup, and big cooking spoons, and my choice is the dessert size. Mine cost me about 5 cts. in a hardware store, and is made of iron with a plated surface. As I held it in my hand trying to figure out how the melted wax would flow from its lip, my mind went back to the "cruise" of fifty years ago—that is to say, the holder for the melted fat and cotton or vegetable pith that did duty as light-producer in the cottar homes of Scotland. In general outline it suggested a Bartlett pear divided the long way, the core and meat being removed. So I decided to shape my dessert-spoon along the same lines, which was accomplished by the free use of pliers and hammers.

So please picture to yourself the main part of the body of the spoon being used as a reservoir while the sides at the point are folded inward so as to form an open ditch about  $\frac{3}{8}$  inch wide through which the wax may flow.

While the melted wax is being poured on the frame this must be held upside down with the sheet resting on the under side of the top bar. A support of some kind is emphatically necessary. My first was an experimental one to hold only one frame at a time; but once I had got the angles to my mind I made another to hold three.

Make a solid board frame of  $\frac{3}{4}$ -inch lumber, 20 by 24. Diagonally across the face of it nail three cleats of the same thickness any convenient width, not more than an inch, the left ends (provided the cleats run clear across the board) being 3, 10, and 17 inches from the top, the right ends 10, 17, and 24 inches. Then, for plain frames of  $\frac{7}{8}$  top-bar, make from  $\frac{3}{8}$ -inch boards, such as one finds on boxes, three pieces slightly smaller than the inside dimensions of the frame, say 4 by 16. For Root frames the thickness should be  $\frac{5}{8}$  inch. Nail these half an inch above the cleats, and the rack is ready. When in use mine stands on the bench with a slight backward tilt, being supported by a brace that is fastened to the back.

The wax is melted in a large jelly-glass that stands in a five-pound lard-pail containing water almost to the top of the glass. A small kerosene-stove is a convenient source of heat. The spoon usually rests in the water when not in use, so as to keep it warm and clean.

Every thing ready, three frames are placed on the rack upside down; then sheets of foundation are slipped into place. It pays to handle the sheet with great care so as to keep it perfectly flat and the edges straight. The best edge is dropped on the frame so

that there may be perfect contact all along the line.

Dip the spoon in the melted wax and take up about half its capacity. Bring it quickly to the left end of the top bar; turn the handle of the spoon away from the body and pour out the wax, at the same time running the spoon from one end to the other. The left hand, slightly resting on the upper edge of the foundation, presses it down on the top-bar, and at the same time the lip of the spoon presses the lower edge against the board, thus getting perfect alignment. The bar being on a slope, the melted wax runs rapidly downward, just enough being caught in the depressions of the foundation to make a perfect cement.

When all three sheets have been fastened, the frames should be reversed and the melted wax applied on the other side.

Lastly, a word of caution as to the handling of the frames once the foundation has been fastened. The wax sets very speedily, but it takes quite a while to harden, so the sheet of foundation must never be out of perpendicular. To reverse the frame, lift it off the rack and turn it slowly end for end. When the second application has been made lift the frame by both hands; lower one until the top-bar is perpendicular then change hands and bring the top-bar horizontal, proper side up.

The hive is, of course, the best place to store the frames until they are wanted for use.

Victoria, B. C.

## THE LEGAL CONTROL OF BEE TERRITORY.

### An Actual Case where No Law could Help Matters.

BY J. L. BYER.

With a good deal of pleasure we have read what Dr. Miller has to say in defense of his position on the question of the legal control of bee territory and before going further I wish to make it clear that, while I may have intimated in a former article my inability to understand the doctor's attitude on this question, yet I never for a moment questioned his sincerity and honesty in the matter. I am placed in quite a difficult position in attempting to combat the arguments advanced, from the fact that the proposition on which Dr. Miller bases all his theories on the question at issue is, in our opinion, entirely untenable. I refer, of course, to the statement made by him that "if ever bee-keeping is to stand upon a firm basis like other lines of business, there must be such a condition of affairs that the bee-keeper shall feel just as secure against interference as the stock-raiser who is assured by the law that his fields shall be occupied by his cattle and his alone."

With all due regard for the opinion of others, I hold that the two cases are not at all

parallel; for before the stock-raiser has such privileges he must either own the land or pay an adequate rental for the same—something that it would be impossible for a bee-keeper to do in the many thickly settled communities where so many bees are kept to-day. As regards Australia and some other sparsely settled sections, we admit, as we did in a former article, that legal control of territory for the bee keeper might be possible; but, as pointed out in that same article, conditions that are applicable in such places would be entirely impossible in the more thickly settled communities.

I have already stated that I regard the doctor's "foundation stone" as an impossible proposition in so far as bee-keeping is concerned, and I may as well say at once that my belief is that all who contemplate going into bee keeping as a business may as well realize at the first that it is a business of many uncertainties, and be prepared to cope with the overstocking and other problems incidental to the calling, just as miners and others engaged in uncertain occupations expect the various ups and downs natural to the work from the very nature of the same. After all is said and done, it is gratifying to know that very few real bee keepers do encroach upon others, as here in Ontario, at least, it is quite rare to hear of a man moving bees near another who has located before him. At present I can recall only one instance that has come to my notice, and in that case one of our extensive producers moved right across the road from another bee-keeper; and I wish to say most emphatically that, unless there were mitigating circumstances that were not revealed to me, the bee keeper who did the moving is about fifty per cent less of a man, in my estimation, than he was before I heard of the matter. As we have never been in the locality where this happened, all we have on the subject is second-hand, and we do not feel as well qualified to speak as though personally aware of all the facts.

The supposition that Dr. Miller advances regarding Mr. Jones moving to a locality suitable for maintaining 100 colonies, and then having another man move in near him with an apiary, is unfortunately too true in reality in some few cases; but when we go to *suppose* what would happen in a settled community where there were a number keeping bees, if a law were passed giving control of all the territory to *one* man—well, language fails me, and I can only appeal to imagination.

"There's no such conflict about a cow pasture; and why should there be as to a bee-pasture?" As we have already stated, the cow man, in order to get such exclusive rights, either owns or rents *all* the land his cows roam over. Let a bee keeper comply with these conditions, and then the two cases will in a slight degree be parallel, and not before.

Right here at my home I have a case that is not in the supposition class; and after explaining the matter I will ask Dr. Miller to

mete out justice on the theory of each bee-keeper owning his own territory. More than 60 years ago my grandfather had an apiary of 100 colonies, or thereabout, where my home apiary is now established. Right across the road, about a quarter of a mile away, his brother, my great-uncle, had a like number of colonies. If I remember my grandfather correctly, he started with the bees a year or so before his brother did, and I want Dr. Miller to note this fact, for this means that I should have prior rights to the field. In course of time both of these men died, and my father kept bees at the home yard while a son in-law of my uncle now has bees in the yard across the road. As already stated, my home yard is where my grandfather's bees were standing 60 years ago; and while, in former years, there was no apparent overstocking, yet now in the matter of spring feed there are entirely too many bees on the range. To get around this difficulty I have for the past few years been moving away part of the apiary in the fall, bringing them home again at the opening of the alsike flow. This, of course, means a lot of work, and, from a selfish point of view, I might wish that my relative across the road would reduce the number of his own colonies, or else that a law were passed giving me, as the exclusive bee-keeper, the rights to the range. As he has a farm as well as the bees, it is not at all likely that he will ever move away nor yet discontinue keeping bees; and, indeed, under the circumstances I have never considered such a thing in the least probable. What do I intend to do in the matter? Why, some time I expect to get a new location and move to it, even if it does cause me considerable expense and inconvenience. That course, or putting up with present conditions, is my only alternative, and really I do not feel like blaming anybody about it either. But *suppose* both of us decide to stay on the job, and go on increasing these two apiaries—how would any legislation regarding the control of territory work out in our cases? It certainly would need the judgment of a Solomon to decide the matter. To complicate the case further, there are, at a conservative estimate, at least forty farmers on the range in question, most of them owning their land and growing alsike. *Suppose* the majority of them are keeping a few bees, which in the aggregate make up quite a number on this already stocked locality, how would the proposed legislation work in their case?

The illustration given is not at all an exaggerated picture, as there are many cases just as complicated as this that would be revealed if ever such a thing as legal control of bee territory were thought of. The more I think of the matter, the more it appeals to me as being utterly impossible that such a law as advocated by Dr. Miller would ever be workable; and this being the case, I too would end this article with the same words as he did his, and warn all prospective bee-keepers that "No bee-keeper in this land has a legal right to his bee territory;" and may I

be pardoned for appending the prophecy that he is not at all likely ever to have such an assurance?

Mt. Joy, Ont.

STRUCTURE OF THE HONEY-BEE.

A Lantern Lecture by C. P. Gillette, of the Colorado Agricultural College.

*Delivered before the Annual Meeting of the Colorado State Bee-keepers' Association, December, 1909.*

[Bee-keepers are often surprised to find that the subject of apiculture is so interesting to the members of farmers' institutes, or even to a popular audience. We have mentioned a good many times that it pays a bee-keeper well to give talks on the subject of bees, and many have followed our advice with both pleasure and profit. We have had a number of requests for scientific data arranged in an easily understood form, and we are very glad to place this article by Prof. Gillette in these columns, knowing that it supplies this information in a popular form that can be easily made use of by those who desire to give practical talks on apiculture.—ED.]

Without the pictures this address can be given only in part. The following is a brief extract from what was said.

The honey-bee is, with the possible exception of the silkworm, the most important commercial insect. Although the bee is handled and cared for throughout its life by man, it can hardly be considered a domesticated animal. A colony of bees in the apiary differs from a colony of wild bees in a beehive or a ledge of rocks only because of the difference in the home they dwell in. The insect intelligence is not capable of being taught as one might teach a dog or a horse.

Bees do wonderful things to provide for their home needs and the care of the young; but they do all from instinct, and not from education received from others after they are grown.

The social habits of the bee are greatly to be admired. The family, though very large, numbering thousands, live together in the utmost harmony. The bee colony is often referred to as a true commune where each colony is a single family, and each family, consisting of one mother and her children, will oppose to the death the intrusions of neighbors, although these neighbors may be of the closest blood relationships, perhaps first cousins, or even full sisters that left the home a few weeks before to start a home of their own. So, between families the bee is not a communist at all.

There are many species of wild bees that are not used for commercial purposes, and many species of ants that, like the honey-bee, live in colonies, but in no case do these social insects permit members of other colonies to enter the home and disturb the property there collected.

There are a great many fossils of insects found in rocks of the earth's crust that must have been formed at a time long before man inhabited the earth. It is altogether probable that our honey-bee was present upon the earth gathering nectar and pollen, cross-fertilizing plants, and caring for its home, be-

fore the earth was in a condition to be inhabited by human beings.

We are also interested in the honey-bee because it stands at the head of its class, thus ranking in the insect world with man in the realm of higher animal life.

The honey-bee is a true insect, and is built upon a very different plan from that of the higher animals with which we come in contact. The body is divided into three very distinct portions—the head, containing the organs of special sense and brain; the thorax, which is the muscular portion of the body, and to which are attached the legs and wings for locomotion; and the abdomen, which possesses the organs of digestion, reproduction, and, for the most part, the organs of respiration and circulation as well. The number of legs in the adult insect is six, a number which we do not find in other forms of animal life. The heart is a mere tube with openings along the sides for the entrance of the body fluid, or blood. This fluid is forced forward by the pulsations of this tube, and poured out into the body cavity again to bathe the tissues. Insects do not have a closed circulation.

The nervous system, which lies near the dorsal surface in all vertebrate animals, lies close along the ventral surface in the honey-bee, as well as in all of the insects. The honey-bee breathes, not through nostrils located in the head, but through small openings called spiracles, which open along the sides of the thorax and the abdomen. Holding the head of a bee or any other insect under water would not in the least interfere with respiration. There are no lungs. The air taken in through these spiracles is carried by minute branching trachea to every living part of the body, where it supplies oxygen to the tissues and takes away the poisonous carbonic-acid gas. So the honey-bee never has pure and impure blood side by side. The blood is all the time kept pure.

The honey-bee possesses about the same organs of special sense as we find in higher animals; but these organs are built upon very different plans. That the bee can see, smell, taste, and feel there can be no doubt, and possibly it can hear also, but upon this point there is some reason for doubt. Nature provides only such organs for its numerous creatures as are specially needed. The bee must see and smell or it could not find the flowers from which the food is obtained, or both the young and the adult members of the bee family. It might be well to remember that all color in flowers, as well as all odor, is for the purpose of attracting the honey-bee and other flower-visiting insects to carry pollen from blossom to blossom for cross-fertilization. The flowers that do not need the insects to carry pollen in this way have neither beautiful colors nor any aroma to attract the insects, nor do they secrete nectar. If the flower blooms in the evening or very early morning, it is white or light yellow because these colors are most plainly seen in the dim light. If the color and size of the flower are such as to make it incon-

spectuous, then the odor is very strong so as to compensate for the lack of size and color in attracting the insect visitants.

Bees, like most other insects, pass through four very distinct stages in their development—the egg, the larva (or growing stage), the pupa (or resting stage), and the adult. The adult bee lives a few weeks only during the summer season; but those bees that mature late may live well into the honey-gathering season of the following year.

The bee, being a skilled workman (or workwoman), has highly developed instruments for carrying on its work. Among those that were shown upon the screen were the large compound eyes to see well with by daylight; the little ocelli, better adapted for vision where very little light is present; the eye-brush, used to clean all dust from the compound eyes that the vision may be clear; the compound hairs found only upon those bees that gather pollen, and especially adapted for the purpose of entangling the pollen grains as the bee tumbles about in the flower; the brush, by which all of these pollen grains are collected to be placed in the pollen-basket; and many other very interesting structures.

While the bee is of great commercial importance to man as a gatherer of one of the choicest sweets that we have upon our tables, it probably does even greater benefit in the cross-fertilization of the flowers of our agricultural fruits and plants, and so cause larger crops. There is some question, however, whether or not the honey-bee greatly increases the yield of alfalfa seed, as the flowers of this plant seem to be able to fertilize themselves without the assistance of visiting insects.

---

## RESULTS OF BEE-KEEPING LEARNED FROM BOOKS.

### A History of a Beginner's Mistakes and Experiences.

BY MARTHA K. PURSELL.

I have studied the theories and read the practices of bee-keepers until it seems I have all that books can give me. "Langstroth, Revised by Dadant," "Quinby's New Bee-keeping," "The A B C of Bee Culture," Miller's "Forty Years among the Bees," "Advanced Bee Culture"—these have been my text-books.

To look back on the work of the last few seasons is to laugh. It was a blind effort to use book methods without knowledge of underlying principles—a succession of mistakes, with changes often enough to prevent total loss.

#### CHAPTER ONE.

In the early spring one year I was in a run down condition of health with a pocket-book to match. How to change these conditions became the question. My physician said I should be more out of doors. My home, on the outskirts of a suburban town,

offered a suitable location for bee-keeping, so I finally decided to try that.

The initial proceeding was to subscribe for GLEANINGS. In order to understand terms used several good books were read. This reading only showed how much I had to learn. I then subscribed for the *American Bee Journal* and the *Review*. Back numbers of GLEANINGS and the *Review* introduced me to Miller, Doolittle, Alexander, Townsend, and all the other lights of varying power which illumine the world of bee-keepers.

The diversity of methods seeming at first to contradict each other was a source of much confusion of mind. I worked at first, as many in every line continue to do, by the rule of thumb. My first order for supplies was:—

- 1 ten-frame hive nailed and painted, full sheets.
- 5 " " " in flat. full sheets.
- 1 Danz. super ready for use, full sheets.
- 1 standard smoker.
- 2 honey-boards.

We had an opportunity of witnessing free demonstrations on a roof in Philadelphia. My twelve-year-old son, destined to be my assistant and successor, and myself were soon on hand to see how bees were handled. On May 15 we carried home a four-frame nucleus with queen. This is hive No. 1.

Before the supplies arrived I ordered from a local breeder of golden bees a two frame nucleus and queen. These were to be called for on notice. The season being unusually late they were not received until May 25. Hive No. 2.

Later purchases of bees were as follows: On the last of June a one frame nucleus with extra bees and fine queen bought by the boy when the roof apiary was closed for the season. Hive No. 3.

A box hive of black bees purchased in July of a neighbor was drummed into a ten-frame hive filled with nine foundation frames and one comb from No. 3. Their queen was lost, but they raised a fine Italian. Hive No. 4.

June 28 we attended a field meeting, and there heard that the season was over. We had supposed that there was always honey all summer, and wondered what No. 1 would do now if it grew strong. Perhaps it would swarm with the fine queen. We would prevent that, and we did, to our sorrow.

When it became apparent that we would get no honey from No. 1, our only hope, the gibes of the family determined us to get honey somehow; so I paid \$6.00 to another neighbor for an eight-frame hybrid colony. This neighbor had been keeping bees for several years, and assured me that he usually secured as much honey in the fall as in the spring. Result— all field bees returned to their old home. On examination, neither eggs nor queen was found. After waiting twelve days to see if the stray virgin had mated, we found no queen. Sent the boy to town to buy a fine Italian queen; introduced on the candy plan, only to find it dead a few days later. Growing desperate at this delay, but still hoping for honey, I inserted a cell raised in a baby nucleus from the egg. The queen resulting was superseded the fol-

lowing spring. Can you wonder that it gave us no honey and required feeding for winter? Hive No. 5.

The purchase of a queen Sept. 1, when the Ferris plan was so large on my horizon, completed the amount spent for stock during the year, which was \$25.50. This, and a bill for supplies, used and unused, of \$20.85 was on one side of my ledger and the other side was blank.

#### MISTAKES OF THE YEAR.

1. Putting in all the full sheets of foundation before they were needed.

2. Trying to get most of it drawn out by giving every nucleus a full set at once. Some of it was chewed into holes or propolized.

3. Changing to sectional hive too late in the season, and when the colony was not strong.

4. Trying to raise a queen in a nucleus from the egg.

Colony No. 1 could have been made to produce extracted honey if a shallow super had been given over a contracted brood-nest, as the ten frames were filled with honey when it was broken up, in an effort to change to sectional hive.

By the time winter set in, the bees were in this shape: No. 1 had ceased to be. This had been transferred late into one part of a sectional hive, and was thought to be strong enough in bees and stores to winter, but was found queenless and dead.

No. 2 was strong and full of stores.

Nos. 3 and 4 were in a ten-frame hive with partition between, *a la Ferris*.

No. 5 had a poor queen, and had to be fed for winter.

No. 6 was another hive, *a la Ferris*, made up from combs of No. 1, No. 3, and No. 4, with queen purchased in September in one side, and one raised from cell found in No. 1, after her queen had been killed in needless changes, in the other.

*To be continued.*

#### REMOVING BEES FROM THE CELLAR.

**A Cold Day Should be Selected in Order to Prevent the Bees Stampinged.**

BY J. E. HAND.

It will soon be time to remove bees from cellars, and begin preparations for a bumper crop of clover honey, for which the prospects never looked brighter than now. All the clovers went into the winter in excellent condition, and the heavy blanket of snow has kept them so. Bee keepers have every reason to be encouraged, and should put forth every effort to make the season of 1910 a record-breaker for honey production.

A good start is a long leap toward winning the race; therefore our success will, in a great measure, depend upon giving our bees a good send-off in the spring. This is very important. A mistake made at this point can not easily be rectified, and the result is often a lot of weak and unproductive colo-

panies that might have been profitable honey-producers had the bee-keeper performed his part in an intelligent manner.

#### WHEN TO REMOVE BEES FROM THE CELLAR.

The time of soft-maple bloom is usually considered the right time to remove bees from the cellar. Begin operations in the afternoon of a cold cloudy day, when the prospect is good for continued cold for two or three days. When a warm day comes the bees will fly out naturally, and, in the absence of any excitement, will mark their location and return to their respective hives. There will be no drifting, and, best of all, no robbing.

If bees are removed from the cellar on a warm sunny day there is bound to be a mixup, which is little less than a stampede. Bees will rush from the hives without marking their locations, and return to some other hive to which they may be attracted by an unusual commotion, and thus some hives will become jammed full while others will be weakened to such an extent as to give them a serious setback. Robbing is sure to begin, and will cause more or less trouble and vexatious losses until the honey-flow begins; for a bee once a robber is always a robber, and is good for nothing else. All this trouble may be avoided by exercising a little care and starting right.

When the bees are removed from the cellar it is a good plan to spread burlap sacks over the hive and push a telescope cap down over the whole hive and let them severely alone until settled warm weather. Nothing is gained by spring tinkering with bees except to feed liberally any that may be short of stores.

Birmingham, O.

[We particularly indorse our correspondent's recommendation as to the *kind* of day when bees should be taken out of the cellar. Beginners who have bees to take out would do well to follow these directions carefully.—ED.]

## THE BEST PLACE FOR BAIT SECTIONS.

### Comb vs. Extracted Honey.

BY CHAS. D. WEST.

Since my brother was killed (in July, 1907) I have been in the bee business with my father, Mr. N. D. West. We are running 500 colonies, all for comb honey except 80, which we run for extracted. We use an eight-frame automatic extractor run by a gasoline engine. We find it saves us time and labor. The engine is also used to run our saw. Until we bought the engine and extractor we did our extracting by hand, and our saw was run by horse power. The engine is safer and more convenient.

In the Jan. 1st issue I read an article by H. E. Crowther, on the best place to put bait sections. If he will pardon me I will make an infringement on it (not a criticism).

#### WHERE TO PUT THE BAITS.

I am inclined to think the center of the super is the best place. We have also used bait sections both ways, and obtain better results in the center. Bees usually begin their work in the center of the brood-hive where most of the eggs and brood are found. If a hive is opened on a cool morning, most of the bees will be clustered in the center of the hive, where the brood is usually the thickest. If the cover is raised from the supers on a cool morning, and the bees are there, they will be in the center of the super, even when no bait sections are used.

The hive we are using needs two supers to cover the top; and by using the bait sections in the center it requires only half as many. After the bees are up in the sections, and working well, they will stay there as long as the honey-flow is good and they are kept strong.

#### THORNS FOR SUPPORTING FOUNDATION.

Mr. Crowther's idea of the short splints in the top-bar to prevent the foundation buckling is a very good one. A few years ago, I remember, my father used long thorns in the top and end bars to prevent buckling; also to serve as supports to keep the foundation from falling out while being carried from one place to another and while handling. Since bee diseases have been in this locality, we have discarded the use of the thorns, and use foundation which is wired vertically and horizontally. This keeps it from buckling. The thorns sometimes bother about removing the combs when they are to be made into wax or when they melt out.

#### EXTRACTING SUPERS OVER EXCLUDERS.

Until the last three years, we have run, for comb honey, about 500 colonies in five different apiaries. The last three years we have been running one apiary (our home apiary) of 80 colonies, for extracted honey. From this yard we get more honey with less work. The production of extracted is not only labor-saving but can be looked at from the financial standpoint as well. One hundred good colonies run for extracted honey will produce more pounds of honey than the same number run for comb honey. The past season we got more honey from 76 run for extracted honey than from 100 which were run for comb, about two miles distant.

Excluders do not interfere with the storing of honey. As early in the spring as the bees are strong enough we put on a super of extracting-combs *without* the excluder, and let the queen lay in the super as well as in the brood-chamber if the combs above are in proper condition. By this method there are two hives of brood, which are better than one. Of course, this super must be put on in time. The queen, after the super is full of brood, is put in the lower hive, with the excluder between. The brood in the super is allowed to hatch in time to help gather the honey-flow which is to be on hand soon. By using this plan the colonies will be a half stronger in bees.

This is also a fine way for making increase.

By having bees hatched in the super they will return to that part of the hive with the nectar which they gather. This induces the bees in the lower hive to store the honey above, and save the lower combs for brood. Middleburg, N. Y., Jan. 24.

[It is generally conceded that more extracted can be produced under the same conditions than comb honey; but how much more is a mooted question.—ED.]

---

### "DRIFTING" AFTER MOVING OR SETTING BEES OUT OF A CELLAR.

What is "Drifting"? A Discussion of the Conditions which Cause it, and the Remedies.

BY R. F. HOLTERMANN.

The question often presents itself, as to how we can prevent bees, under certain conditions, from drifting. By "drifting" is meant the tendency bees have to fly out of their hives in considerable numbers, and, instead of returning, go to a new location in the apiary. This may result in the bees being attracted to the most populous colonies, or possibly from one end of a row to another, or from one side of the apiary to the other side. This condition occurs most frequently during the first flight in the spring, particularly when the bees have been wintered indoors under unfavorable conditions. Another occasion for drifting is when bees are moved from one location to another in the summer. There is also, in rare instances, a tendency to drift when a swarm issues and returns again. The bees of such a swarm scatter somewhat into every hive in a row, etc. This latter, however, does not come properly under the occasions for drifting, although we will consider it later.

To remedy the conditions given we must find the causes—the principal one, in my estimation, being excitement on the part of the bees so that they do not mark their location as they leave the hive, and move, therefore, toward a stronger attraction elsewhere, which attraction generally consists of flying bees or clustered bees that are visibly attracting others to them.

Another cause is the wind, which may blow the bees to one side of a bee-yard, and, as they recover control of their motion, they collect in front of the most convenient hive, and the one manifesting the most life, having forgotten or lost their own entrance; and as the flying bees increase in numbers, others keep coming. This is particularly true when colonies are set out of a cellar after having wintered poorly, when the consequent rapid changes of conditions from inside atmosphere to the outside increase the excitement of the first fly. The proximity of one hive to another has an important bearing on the matter, as does also the order in which the hives stand, the bees of hives standing in rows being perhaps more likely to drift.

### MOVING BEES.

When bees are moved from one location to another during hot weather, to a new pasture for instance, so that they have been confined to the hive, they get excited, especially if they are confined when it is light, and if, during the day, the hives are opened, the bees are quite likely to drift—perhaps in several ways. The end of the row at which the hives are first opened is the end toward which they naturally turn. After that, unless enough time has elapsed so that the first uproar has quieted down, within moderation at least, one may open the hives anywhere, and yet the bees will keep drifting toward the end where the first and greatest excitement is, although they may follow a row. The principle in drifting appears to be this: A temporary excitement causes the bees to forget the instinct of returning to the place they left, so that they are drawn to the new home by other interests. It is always a question in my mind as to whether bees would not return to their own hive if the conditions were unchanged since the last flight. By this I mean that, if every colony is set out from the cellar and placed on the stand occupied last year, would not the bees, after an excited flight, be more likely to return to their own hives? Or if, after colonies are moved in the summer, would the bees have less tendency to drift if the hives are set in the same relative position to themselves and the other objects?

### REMEDIES FOR DRIFTING.

In setting out colonies in the spring, if the cellar can be well aired the night before, and the hives set out before daylight, on a day when it is no warmer than necessary for safe flight, and preferably on a cloudy day, if warm enough, the conditions are not favorable to drifting. The fewer colonies set out at one time the better, and the further apart the hives are placed the less the bees are attracted by other colonies. If a bee-keeper does all in his power to secure these conditions I think he has done his best. I have said nothing about securing ideal wintering conditions; for if a bee-keeper has not already attended to this there is no use in suggesting to him any thing of the kind, for it is too late.

Some may ask how they can secure all the above combinations; but it is not for me to say how, for, as in many other things, we have an ideal or pattern, and our skill and experience must aid us in attaining to it.

When colonies are moved I like to set the hives on their new stands during the night. Then after the entrances are opened the bees quiet down before trying their first flight. In my experience this has always prevented drifting. When this can not be done, an excellent plan is to sprinkle the bees well with water before the hives are opened; and if they get a light shower bath as they come out of the hives, all the better.

### DRIFTING OF BEES FROM A SWARM.

Jacob Alspaugh once said to me that if the hives were close together he would prefer not to clip the queens' wings, for he would

rather lose an occasional swarm than to have the returning bees of a swarm from a hive with a clipped queen scatter, as they often do, into other hives, so that, if these other colonies are strong, they too are likely to get the swarming impulse. Mr. Alspaugh said further that he had marked quite a number of hives into which bees from returning swarms had entered, and these colonies soon wanted to swarm. The only way in which I can explain the action of the bees of a normal swarm, when returning on account of having a clipped queen, and entering other hives, is that there is a stronger attraction than that at the old home. In such cases the bees seem to be determined not to go back to the old location.

Brantford, Can.

### WHITE-CLOVER PROSPECTS.

**A Bumper Crop Predicted for 1910; if the Clover is in Good Condition Nov. 1, of any Year, Prospects for a Honey Crop are Favorable for the Following Season.**

BY VIRGIL WEAVER.

[Mr. Weaver is the man who predicted a scant white-clover honey-flow in 1909, and who, in spite of the opinions of nearly all of the writers to the contrary, held to his prediction until the season proved that he was right. He believes now that, in most localities at least, there will be a record white-clover yield in 1910. In view of his past record, the following article deserves careful attention.—Ed.]

I began bee-keeping in 1893. I had read Root's A B C, Doolittle on queen-rearing, the bee journals two years, and had studied bees nearly all my life. I ordered 25 hives from the Root Co., and purchased ten colonies of black bees in box hives; transferred them to eight frame hives, and patiently waited for the honey-flow. Very little clover showed up; no honey was harvested; so by studying the bee periodicals closely I came to the conclusion that the clover had winter-killed. When 1894 came I had 17 good colonies. We had a very mild winter, so felt pretty sure that the honey-flow would be good. The conditions in the spring being very favorable for the growth of white clover I could not see why the honey failed. Then 1895 and 1896 gave the same results. Four failures in succession reduced my bee fever to the 80's, and I was just about ready to give up. One thing I had noticed was that, preceding each of the years mentioned, it had run from very dry to moderately dry, especially in July and August. The year 1896 changed the program exactly. We had a dry spring; July gave a rainfall of 8 inches; August more than 6, and September was very little better, giving about 5 in. The winter following was about normal; the spring of 1897 was very favorable, and the honey secured from white clover averaged 150 lbs. per colony. The year 1898 gave 100 lbs. per colony, and 1899 gave 300 lbs.; the winter of 1898 was the coldest on record in my locality, zero weather extending into March, freezing and thawing continually. This 300 pound yield after so severe a winter was a little

contrary to the teaching of most of the old bee-keepers, and right here I began watching for the combination that it took to make a honey-flow from white clover. Prior to this time I shared the opinion of other bee-keepers, that conditions are nearly always normal for a yield from white clover on Nov. 1, and that the winter months virtually control the honey-flow. But by watching very closely, and also studying Weather Bureau statistics, I have learned that, if white clover is in a normal condition Nov. 1, it is also in a normal condition April 1, and that the winter months have no more to do with the white-clover honey-flow than Adam's off ox.

On May 9, 1907, I wrote an article for this journal, telling the bee-keepers of the northern part of the white-clover belt that there would be nothing doing in the white-clover line that year, but that in my locality, and the southern part of the white-clover belt, our prospects were good for a flow. That year I sold 22,000 lbs. of honey from 180 colonies of bees. To bear my former statement out, N. E. France said that he could count on his fingers all the parties who had a honey-flow that year. In the spring of 1908 I made no honey forecast, because, being located on the southern side of the white-clover belt, I was hopeful of getting some of my honey off at the high price before the deluge came from the North—something I was mistaken in. In February 1st GLEANINGS, 1909, I had another article, telling the bee-keepers that east of the Mississippi River there would not be a tenth of a white-clover crop that year; but didn't Miller, Root, Doolittle, Hand & Co. do me up! What was the result? The editor, after bringing in Canada, which gave a yield from alsike clover, and including all the alsike and sweet clovers and basswood honey, said that there was from 25 to 50 per cent of a white-honey flow. Now, if you will except the above-named sources it is a serious question in my mind whether there was a single carload of surplus white clover honey gathered from the Mississippi to the Hudson River.

Now I have a different story. Instead of no honey, I want to say that there will be a bumper crop this time in most of the clover belt east of the Mississippi River. When I say "white-clover belt" I mean those localities where white clover grows spontaneously. The best of these localities are the Blue Grass sections of Kentucky; Ohio, Indiana, Illinois, Missouri, Iowa, Southern Minnesota, Southern Michigan, and Southern Wisconsin—Iowa and Northern Illinois being the heart of this belt. Draw a line from Dubuque, Ia., to Springfield, Ill., thence to Indianapolis, Ind., thence to Louisville, Ky., thence south; in nearly all the white-clover belt east of this line the white clover is in a normal condition; i. e., a crop of white clover started from the seed in the spring of 1909 which grew continually, caused by a surplus of rainfall, and, under favorable conditions, will produce one of the largest honey-flows on record in 1910. The honey crop for 1910 now depends on normal rainfall and sunshine

after May 15, not on the amount of snowfall or freezing and thawing we have during the winter months. The snow helps in just this way: It leaves the ground with plenty of moisture in it in the spring, thus inviting more moisture when the clover has got to have it. The condition west of this line is just this. The clover here was cut off from moisture about July 10, and has set only a moderate amount of embryo blossoms to bloom this year; and the best that can be hoped for in this section is a moderate yield. The reason I say this is that July and August are the most important months in setting embryo blossoms for next season's crop of honey; and the greater the rainfall in these months, the larger amount of embryo blossoms set. At this period the other grasses are taking a kind of rest. Blue grass has set its crop of seed; the meadows have been shorn by the mower, and have not started yet on a new crop of fall growth, thus giving a crop of new white clover a chance to spread itself, which, with plenty of moisture, it certainly does to a king's taste. In a great many places of this section the rainfall almost vanished after July 10—Cairo, Ill., for example, giving but a trace of rain for August. West of the Mississippi and South of the Minnesota line conditions are not very favorable for white-clover honey. Iowa is hit hardest, as there are whole counties in that State that will not produce a pound of surplus white-clover honey this year. I have no government data covering Missouri and Kansas; but through an unofficial source I have learned that a good part of these States were hit hard by fall drouths in 1909, there being about seven weeks without rain, beginning July 10, in large areas of this section. In Missouri, as there was no honey last year to speak of, and where the rainfall was excessive until July 10, there ought to be some honey this year. I want the snow-honey fellows to watch Iowa this year. The ground there in most parts of the State has been covered with snow since Dec. 1, and I say that there will not be half a yield from white clover in that State in 1910. Snow does not set embryo clover-blossoms. It takes a temperature from 75 to 90 degrees, and from three to six inches of rainfall per month to do the work.

I will now tell what kind of weather we need to make a bumper crop of honey in 1910. As I have said before, wherever the clover is in a normal condition Nov. 1, it will be in a normal condition April 1. To get best results after April 1, could I have my own way in my locality I would have good rains to soak the ground thoroughly as soon as warm weather comes, the last rains to be May 1; then I would have three weeks of dry weather—this to make the clover fill the ground with feeders to gather plant food and moisture; then I would have good rains to soak the ground thoroughly again; also as much as an inch of rain every eight or ten days; then we would see the greatest yield from white clover that any combination of circumstances could make.

Now, it may happen that, where the clover is not in the best condition now, conditions will be good for a honey flow; and where conditions are most favorable now for a lack of or from too much moisture, it may cut the honey flow short; but taking conditions as a whole, to have clover in a normal condition Nov. 1 is five points out of ten in securing a honey-flow.

In speaking of a normal condition for white clover, there are two conditions where clover is in a normal condition, one which occurs but about one year in five. It occurred in my locality in my 17 years of bee-keeping as follows: 1897, 1902, 1906 and 1910. At Dr. Miller's it occurred 1897, 1903, 1908, and 1910. Now, as it will be two or three years before this condition can occur again it makes it for the two locations about one year in five as stated above. This condition is a crop of white clover, the greater part of which has started from the seed the year previous, and has covered the ground thoroughly with plants that are in the best condition that it is possible to put them in. These are the plants that, under normal condition, in the best of the white-clover belt, will yield honey for three months. The other condition, which is also a normal one, but which at Dr. Miller's, or, in fact, all the best of the white-clover belt, will not produce under the same climatic conditions more than half as much honey as the condition first mentioned. It is where these plants started from the seed in 1909, and have developed a greater part of their blossoms in 1910. Then these plants set new plants from their runners, and these new plants set new embryo blossoms that blossom next year, but the bloom period being about half as long the second year as the first. This will continue for a year or two, then they fall down from overcrowding or drouth. In my locality clover never fails from overcrowding. As I am on the extreme southern side of the white-clover belt our soil is not as strong nor as well adapted to white clover as it is north. There is no combination of circumstances in my locality that will make white clover yield honey later than July 10, while in the best of the clover belt it will yield honey for three months or more.

Richmond, Kentucky, Feb. 28.

## SUPPLYING NEEDED STORES IN THE SPRING.

### Pouring Syrup into Empty Combs Instead of Feeders; some Advantages of the Plan.

BY G. F. SCHIBER.

More than twenty years ago, when Dr. Miller wrote "A Year Among the Bees" he gave in that book his plan of feeding by filling empty combs (regular brood-combs), with sugar syrup and putting them right in the hive. The doctor pointed out that in this way one always has plenty of feeders; for if all the combs are full there is no neces-

sity for feeding; and if they are empty, there are plenty of feeders, of course. He cautioned his readers against allowing any excitement that might bring on robbing, and advised inserting the combs late in the day so that by morning, every thing would be cleaned up. In his later book, "Forty Years Among the Bees," I note that he has abandoned comb feeding, and uses regular feeders instead.

For fall feeding, when one wishes to feed a large quantity quickly the feeder plan may be the best; yet for both fall and spring feeding I still think the combs are the most satisfactory. There are never any feeders lying around in the way and I am never bothered by leaks when I put them in the hives, caused by shrinkage, etc. The real value of feeding in the combs is in the spring. It very often happens that I have a number of colonies that are short of stores when they come out of winter quarters. I realize that it is better to have them fed sufficiently in the fall to last until fruit bloom; but although I have tried to provide sufficient every fall, I have not yet succeeded in having all colonies come up to fruit bloom without more or less feeding. By the way, I do not know how we can make colonies grow any faster than by giving strong colonies an abundance of stores, so that they will never be short during the breeding period preceding the flow. Many times I have lost money by allowing good colonies to go through this trying period a little too near the "pauper line," for just as surely as the sun rises, the queens will slacken their egg laying if the honey is getting scarce and no more is in sight.

I have done but very little real stimulative feeding—that is, feeding a little every day or every other day. I do not know whether this would pay me or not; but if a colony is short of stores in the spring I usually insert two combs of two-to-one syrup, which will amount to six or seven pounds. I do this toward evening, and then, a week or so later, I can repeat the process if necessary. If I have any dark honey I use it up in this way.

I realize that the strain of bees is important; but providing an abundance of stores during the spring months, or at any time when colonies are being built up for an anticipated flow, is important too. It may be urged that filling the combs is too much work; but it is not when one learns how to do it. Dr. Miller, in his first book, described his way of filling the combs by pinching the bottom of a can full of holes and holding this full of syrup over the combs to be filled. I usually follow a method of my own, and it is much shorter than one would think. The syrup should be warmed to about 120 degrees Fahr. I use a large dishpan over which the comb may be inclined at an angle of about 45 degrees, and dip up the syrup with the cup and pour it into the cells, holding the cup about a foot from the upper end of the comb. As the syrup runs down the comb the cells are filled more or less. Then

I keep working down with the cup with a sort of drenching motion, turn the comb over, and repeat the process on the other side. I place the filled combs in a hive-body which stands over a large pan. I never timed myself, but I can fill fifty combs in a very little while.

The colonies that I want to feed are previously marked, each hive being marked with the number of combs needed, and the space for such combs left in readiness. Toward evening, with a smoker, I quickly insert the combs and cover every thing up warm. I have found that bees will take syrup from combs when they will not work in a feeder on account of cool nights. If I had only twenty five or thirty colonies I might take the time to fuss with feeders; but with a larger number it is much quicker and easier to feed in the combs. The more fussing there is to the work of feeding, the more one neglects it. I usually make the syrup a little heavier than two to one; perhaps it is often as thick as three to one. Even in the spring I think it is a good plan to have the syrup at least as heavy as two to one.

Randolph, N. Y.

#### ITALIANS COME OUT IN COLD WEATHER MORE THAN THE BLACKS.

On cold days the Italians are out at work when the blacks are not. On these cold days take some of them to the fire, and they will crawl as soon as they are warm. There is not a week here but that bees can work in winter; but the Italians try to work when they can't get back safe. Some get back home, but fall in front of the hive. If they are warmed they get over the cold; but if not they die.

Hamburg, La.

F. M. MORGAN.

---

#### A FLOOD FOLLOWED BY COLD WEATHER; BEES FROZEN TO DEATH.

On the 15th of November we had very high water which overflowed the bottom lands. I had my bees up on trestles high above the water. I couldn't take them down on account of the still threatening flood conditions. Then there came a sharp freeze while the river was high, and threatening. It turned so cold that ice was 1½ inches thick over the ground. I find my bees are all frozen to death. What had I better do with the combs—melt them into wax or try to get bees and queens and put on them in the spring? I had only eight hives, the flood of 1908 having washed away 35 for me.

AMOS PIATT.

[If the combs are reasonably good we would advise you to buy bees and put on them in the spring. If they are old or crooked, or the frames are poor or a misfit, melt them up.—ED.]

---

#### HAS ANY STOCK BEEN STUNG AT WATERING-TROUGHS?

I wish to inquire if you have ever known of a case where bees that have frequented the feeding-troughs of swine had gotten in the feed, been swallowed with it, and in turn had stung the mouth or throat of the pig, causing complications that resulted in the speedy death of the animal. Or have you ever known of pigs given orchard range being killed by the stings of bees that had been eaten along with the fallen fruit?

Aiken, Md., Feb. 19.

J. FORD SEMPERS.

[We do not recall a single case where any animal—horse, cow, or pig—received a sting in the throat when drinking water at a trough that bees frequented. Even if the animal were stung in the mouth we doubt very much whether any serious consequences would follow. Neither have we known of any case where pigs given the range of an orchard had been stung from eating apples that the bees were visiting. If any of our readers know of a case of this kind, will they please report?—ED.]

## HEADS OF GRAIN FROM DIFFERENT FIELDS

SHIPPING CARLOAD AND LESS THAN CARLOAD SHIPMENTS OF BEES.

We intend to move to Salem, Oregon, about March. We have about 85 colonies of bees; and as we could not dispose of them here to good advantage we will take them, together with supplies. I should like some advice as to packing. Would it be safe to remove both bottom-boards and cover, using screen securely fastened on, and leaving an air-space between hives, say of one inch? Would it be necessary for some one to go with them, or are they just as well if packed well? The railroad companies say they can not give a pass with the car.

Can you give me any information about Oregon, west of the Cascades, as to honey production? Chatfield, Minn., Jan. 31. E. MONETTE, JR.

[We would not advise you to try to ship only 85 colonies of bees by freight from Minnesota to Oregon unless a man went along with the bees. If, however, you are going to send a whole carload of household goods, and the bees can be accommodated in the same car, it might be practical to ship the bees, if there were no transfers, even if the man did not go along; but it is better to have some one present with the bees to give them water occasionally if the weather is a little warm. Usually it is not practical to ship less than a whole carload of bees by freight. The western freight classification requires that a man who accompanies a carload in this way pay regular passenger fare, at the same time sign a contract releasing the transporting railroads from all liability from any injury to passenger riding on such freight trains.

If you ship the bees in March we would advise using only just a screen on top. This should be nailed on a two-inch rim of the same dimensions as the top of the hive. This is for the purpose of giving clustering room under the frames.

Frames, whether self-spacing or unspaced, should be securely fastened in the hive by means of wedges. Hives should be loaded with the frames parallel with the rails. But before putting the hives in the freight car, four or five inches of loose straw should be thrown on the car bottom, hives laid upon the straw, and then secured to each other and otherwise braced in the car. We never advise shipping bees by local freight unless they can go right straight through without transfer to point of destination, and not take more than 48 hours. Even then the hives should be cushioned on straw and securely braced in the car.

When a man goes along with the bees he should be provided with a water-pot, and water the bees every now and then, if they are clustered tightly over the wire cloth. When the car passes over the mountains, loose quilting or something should be laid over the top of the wire cloth to prevent the bees from getting too much chilled.—ED.]

### ABSORBENTS VERSUS SEALED COVERS.

I have read the article in GLEANINGS for Feb. 1 by L. C. Wheeler and your reply. Before the winter closes I wish you would try an experiment; but first I will tell you how I pack my bees for winter.

Over the frames I spread a piece of burlap, and on this I set a chaff tray made like a super, of four-inch lumber, with a piece of burlap tacked on the bottom. This is filled with planer shavings, and they are heaped up in the middle so as to be thicker directly over the cluster.

Last winter I saw the difference between a cushion and one of these trays. When I packed my bees for winter in October, 1908, I was short of trays, so I put into a burlap sack enough shavings so that, when it was spread out over the top of the frames, it made a cushion about four inches thick. In February of last year we had a very warm spell that followed a very cold spell of weather; and when I looked at this hive that had the cushion instead of the tray I found that the cushion was wet and frozen around the edges, and the frames below were damp and moldy. None of the other hives that had trays were that way. I took this cushion off, put on a chaff tray, and in about a week, when I looked again, the hive and packing were dry. I use the Hilton and the Woodman hive, and can see no difference in wintering. The Hilton has thicker walls, but the Woodman is made of heavier lumber.

I wish you would have two or three of these chaff

trays made, and put them on the hives that have the wettest cushions, and see if they get wet like the cushions.

The top layer of shavings directly over the cluster is usually a little damp—much more so with some colonies than others; but the hives are dry and clean in the spring, and our winters are long, and the snowfall is usually heavy—especially so this year.

Benzonia, Mich., Feb. 5. JOHN A. VANDEMAN.

[In our reply to Leon C. Wheeler we did not explain that we were using chaff trays, the same as you are, and that we had been using such trays for many years back. If you were to carry the experience a little further you would find there would not be much difference between a loose chaff cushion, fitting on top of the hive, of a suitable size, and a chaff tray. The only merit of the tray, in our judgment, is that it is a little neater, and makes a little better contact on top of the hive. As usual we are trying several different ways of wintering, using sealed covers and absorbing cushions as well as trays. The result of the experiments will be given in the spring as heretofore.—ED.]

### BEE-KEEPERS' INSTITUTE IN SYRACUSE, N. Y.

On Wednesday, Feb. 9, a bee-keepers' institute was held in the City Hall, Syracuse. This was one of a series of institutes provided for by the State Department of Agriculture to be held in different places, and it proved to be very helpful and interesting as will be seen by the following program:

10 A.M.—Out-apariers, Charles Stewart, Johnstown.

Value of the Italian Bee, M. Stevens, Pennellville.

Sectional Hives, S. D. House, Camillus.

1:30 P.M.—Question-box.

Early Experiences as a Bee-keeper, O. L. Dines.

Wax-rendering, Mr. Stewart.

Bee Diseases, Mr. Stevens.

7:30 P.M.—Question-box.

Wintering Bees, W. D. Wright, Altamont.

Comb Honey, How to Get it, N. D. West, Middleburg.

Production and Sale of Extracted Honey, I. Kinyon.

The morning and afternoon sessions were conducted by Mr. Charles Stewart, of Johnstown. The discussions were directed in such a manner as to bring out the essential points without loss of time, making a live meeting all the way through.

The subjects were well presented, and brought out considerable discussion. Sectional hives, wintering bees, and bee diseases, seemed to arouse the most interest; and in the discussion of bee diseases especial emphasis was placed on the value of the Italian bee as the most important factor in combating black brood.

The evening session was conducted by Mr. N. D. West; and his talk on comb honey and how to get it was given in the convincing manner of the successful veteran producer.

Medina, O.

JESSE A. WARREN.

### IS JAPANESE CLOVER A HONEY-PLANT?

Some time ago I saw in GLEANINGS something about sowing seed of the little Japanese clover for bee pasture. Now if it is what is called Japanese clover here, it doesn't amount to anything for bee pasture. There are hundreds of acres of a plant by that name in reach of my bees, but I rarely see a bee on it. It is an annual, makes a green carpet late in summer, and blooms in September. If it yielded nectar my bees would surely get considerable. It will take to meadows in places, but most of it grows along roadsides and on slopes outside.

Fre蒙特, Mo.

MRS. ALMEDA ELLIS.

[Nearly all honey-plants will fail to yield honey in some localities, and yield profusely in others. For instance, the great honey-plant alfa, that produces hundreds and hundreds of cars of honey in the irrigated West, yields practically no honey in the Eastern States. The same is true of a large number of other plants. It is possible and even probable that Japanese clover is not a yielder of honey.—ED.]

### WHITE CLOVER CAUSING BLOAT IN CATTLE.

In GLEANINGS for Feb. 15 you ask for information in regard to white clover and bloating. In reply I will say that bloating from white clover is not an uncommon occurrence. During the early summer, when growth is heavy, and when it is wet, care has to be exercised when grazing. Cattle put on such pastures about 10 or 11 o'clock, and taken off at 3 P.M., when the clover is dry, are not in so much danger. Violent exercise, or sticking with a knife to let out the gas, is the usual remedy. I believe that alike, under the same conditions, would do likewise.

Lexington, Ky., Feb. 21.

L. E. HILLENMEYER.

## OUR HOMES

By A. I. ROOT.

The voice of one crying in the wilderness.—JOHN 1:23.

Whose end is destruction, whose god is their belly, and whose glory is their shame.—PHILIPPIANS 3:19.

Some of you may be tempted to think me irreverent, dear friends, when I tell you I have long felt that Terry, Fletcher, Sinclair, and perhaps a few others, were in some respects like John the Baptist who kept up his "crying in the wilderness" until the sinful world not only stopped to listen but came to him from "all the region round about," asking what they must do to be saved. Of course, John's message was to a *sinful* world, while T. B. Terry's is mainly to a *suffering* world; but sin and suffering are so closely connected it may be hard to separate them.

I suppose the readers of GLEANINGS have all read the matter on the back cover of this journal for Jan. 15. If you have not, I beg of you to get it and read it at once. Of course, it is an advertisement; but after having read it over several times I decide again it contains a story of more real value to humanity than any advertisement I ever saw before in my life. It was reading this that prompted me to tell you something of what I know of T. B. Terry.

Years ago, when I first began to be really interested in high-pressure agriculture Terry was invited to speak at a farmers' institute in Medina. He gave us a potato talk, and the recital of his experiments and final successes took such a hold of me that I almost insisted he should at once put it into book form. I need hardly tell you that this book proved a boon to the farming world. A big moral comes right in here. Terry raised more potatoes, and better ones, because he made potatoes his express business in life. He seemed to recognize in the outset that, to lead the world in any thing, the enthusiast must have "elbow room." I wonder if our young bee-keepers (and some of the older ones too) are listening. To make a real success in any thing you want to be untrammelled. People laughed when Terry said he didn't want a chicken or a pig on his premises. I believe he also went so far as to say he didn't want a garden. He said he could make his money with potatoes and take this money and buy his eggs, garden truck, etc., cheaper and easier than to try to grow every thing as so many farmers do. All the stuff he wanted passed his house every day, and the neighbors were glad to supply him. Well, potatoes must have heavy fertilizing in some shape, and he soon decided clover turned under was the cheapest and best manure, and he therefore bent all his energies toward getting bigger crops of clover than anybody ever saw before. You perhaps know he has given his clover talks at various farmers' institutes all over our land. To make a proper rotation of crops, wheat came in the same way, and he soon

sold all the wheat he raised in this way, at a big price for seed because it was better and *cleaner* wheat than could be found in the market. As an illustration, he and his help once spent a whole day in hand picking over his seed wheat in order that he might keep his beautiful farm free from foul weeds. I think they got less than a teacupful of weed seed; but he considered it time well invested. He never used poison on his potatoes, because he hand-picked the mother bugs before they ever had time to lay any eggs, and the work cost him less than the Paris green.

He did make one digression in favor of strawberries. Something or somebody suggested that wonderful berries could be grown by turning under that heavy clover sod; and as an experiment, he, with the aid of his good wife and children, raised more and larger and better berries than were ever seen before in that region. Of course they brought a big price, and he saw at once there was far more money in the berries than in potatoes. Why didn't he start a strawberry farm and get rich?

Now, here is another beautiful moral. Terry's mission in this "wilderness" of sin and suffering was not in order that he might *get rich*. I, in one of my visits, talked the matter over with him. If he went into strawberries it would interfere with the education of his children, with his talks at farmers' institutes, with his being of benefit to the world at large; but he *did*, at my solicitation, write the strawberry book, that has also proved a blessing to humanity. As somebody has said of Prof. Holden, the "corn wizard," the man who put corn on the witness stand and made it "stand up and answer questions," Terry made potatoes, clover, wheat, strawberries, etc., stand up and answer questions in a way they had never done before since the world began.

Please pardon me if I refer *once more* to Booker Washington. When he got to the point where he could thank God that he was born black instead of white he said he was a happy man. I do not know that Terry has ever thanked God that he came so near the verge of the grave, but I think he might do so. Had it not happened, the world would not have had this book.

Not only did Terry make potatoes, clover, and strawberries "stand up and answer questions," but he did the same thing with his domestic animals; and his book, "The Winter Care of Horses and Cattle," was the outcome of this. The beautiful heavy farm team that carried the immense loads of potatoes to market were grown and fed on Terry's clover hay, without a particle of grain. His neighbors said it wasn't *hay*—it was just "*wilted* grass and clover." By the way, I wouldn't wonder if the world, at least a part of it, has had better clover hay since Terry's books have been published than they ever had before. Some credit, at least, is due your humble servant for having these books given the world. When Terry made such a sensation with his "clover sod" strawberries I urged him to put it in book form. He

objected, saying he was only a beginner. But I said, "Mr. Terry, you must write it *now*, when you are full of enthusiasm on the subject." He did so; and when he came to revise it, years after, he admitted I was right about it.

Well, a year or two ago I urged him to put in book form his explorations and discoveries along the line of getting out of the darkness and into the light by better ways of living, etc. For quite a time he declared he had no time, with his extensive correspondence, etc. I continued to urge, however, and I gave you notice on these pages when he started on the task. The above explains partly why I am so deeply interested in Terry's books and teachings. No matter where I travel, whether in Northern Wisconsin or Southern Florida, I come across people who tell me with enthusiasm that "Terry's teachings" have given them not only a new lease of life but a substantial addition to their pocketbooks by his simple diet and other sensible advice. With this long preface I wish now to review somewhat the book that is having such a generous welcome at the hands of the great public.

If ever there was a book written especially for our homes this is the one, and I am sure no other book has ever appeared that covers the ground this one does. The opening chapters are devoted to giving the homes of our land more and purer air than the world has ever had so far—not only pure air, but cool or cold air; and last, but not least, *moist* air. It is a little singular, but all makers of incubators are just now coming to the conclusion that this same moist air is one of the great essentials for the success of the incubator. Terry's "humidifier" for keeping the air of the average home always moist is almost a revelation to a great part of the world. Then follow some chapters on breathing and having the clothing so that the whole body has every possible chance for taking in such quantities of this pure moist air as God intended we should take. Next to the air we breathe comes the water we drink, and the reason why we should drink *lots* of pure water. I might go over the whole book in this way; but I want you all to read the book; and if you once start in you will be sure to read it all, for Terry's very plain familiar way is really enticing. Our own copy has been all around our neighborhood here in Florida. Neighbor Ten Broeck took it Saturday night and returned it Monday morning *read through*.

Now, friends, please do not get the idea that Terry is absolutely right about every thing. If so he would be more than human. There is, however, *so much* in the book that commends itself to *good common sense* we can afford to overlook what seems to us a mistake. I think he is a little too severe on the average family physician; but we all know good honest doctors are *all* getting on "higher ground" of latitude. Again, I believe that vaccination, as a rule, is a boon to humanity; the same with surgery for appendicitis, etc. If Terry's plan of living *will* obvi-

ate the necessity of all these things, then of course I shall be right with him.

In choosing my two texts I had principally in mind the sin of overeating—living to eat instead of eating to live, and I do think Terry's vehement protests against banquets, picnics, overloaded tables of rich viands, *everywhere* and *anywhere* are really "a voice crying in the wilderness" for a reform that is needed, and needed *tremendously*.

Now, I know of no more fitting windup for this Home talk than the following which I clip entire from the *Country Gentleman*. You will readily see where my two texts come in; and may God's Holy Spirit go with Terry, Fletcher, Sinclair, and *this* message to the homes of our land.

#### THE RAW-FOOD CULT.

[Mr. Upton Sinclair, who started the packing-house investigation with his sensational novel, "The Jungle," has now discovered that the cure for all human ills lies not only in eschewing meat, but in eating nothing but raw food. Here is his account of this practice and its results, from *Physical Culture*, which he prefaces by saying that he had been an invalid for years when he adopted it.—ED. C. G.]

I have learned that it does not matter in the least in what part of the world one is—whether in the mountains or at the seashore, in Canada or in Florida. It does not matter whether the air one breathes be hot or cold, "night air" or "day air," damp or dry—provided it be fresh, and not air that some other person has already breathed. I have learned also that it is not necessary to take very much or very elaborate exercise. I gave two years of my time to doing literally nothing but trying to get well; and during that time I made it my duty to exercise nearly all day in the open air—riding horseback, walking, swimming, playing tennis, canoeing—and I was never in worse health in my life than at the end of the two years. Now half an hour a day of real scientific exercise suffices me—with a walk now and then when I happen to have some work to visit.

And it is just the same with sleeping. Now six or seven hours suffices for every thing; and in the old days, when I was told that I needed a "rest" I would sleep ten or even twelve hours. And it is just the same with working—with brain-work, I mean. For two years I did almost nothing—I didn't dare. Now I read and write and study twelve hours a day, for as long a time as I feel like it, and it never does me the slightest harm. The "overwork" business is mostly all delusion. It is not overwork at all, but overeating. It is not lack of rest, nor lack of exercise; it is overeating. It is not a debilitating climate nor a damp and "raw" climate; it is everywhere and always some form of the fatal consequences of eating unnatural foods; of eating foods that have been cooked and devitalized; foods that have been refined and deprived of their wastes, so that they stick in the intestines and clog the system; foods that have been softened and made into mush so that they slip down without chewing, and without giving one a chance to satisfy his hunger; foods that have been concentrated and concocted and combined until all the chemists in the country would be needed to tell a man how much of them he really ought to eat.

I used to give way to the claims of "hospitality;" when I went to people's homes I could not bear to make them uncomfortable and to set myself apart from everybody else; and so I was well so long as I stayed by myself, and sick whenever I went where other human beings were. Last winter, for instance, I spent several months in a solitary place in California, working hard and enjoying magnificent health; and then I went up to San Francisco to stage a play, and I accepted some invitations to lecture at the universities; and the boys got me up delightful suppers of fruit salads and peanut-butter sandwiches and ice-cream and cake, and other wholesome and nutritious vegetarian concoctions. So in a few weeks I was having headaches again, and then a cold, and finally wound up on the Gulf of Mexico with a "sunstroke."

In youth I had the misfortune to be fed on many delicious-tasting inventions. I lived in the South, where people are very proud of their cooking. I have said that I was brought up on a diet of fried chicken and hot biscuits and chocolate cake, and so in our home we had to have a servant. When we were in the coun-

try we had to have two, because one found it too lonely. I have no more vivid memories in my life than of these "servants"—strange and perplexing personages who came from the south of Ireland and the north of Sweden, and the middle of Hungary and Japan. The Hungarian ate raw sausage and bacon; the Irish one dropped dead of apoplexy, and one from South Carolina went crazy and threw the salt-box at my mother's head.

There were times in our struggling days—many years, in fact, when we could not afford a servant, and then my wife had to be it. And when she was ill, which was about half the time, the role fell to me. So I know just what I am talking about when I discuss this question of cooking, and what it means to human beings. I have known what it is to build the fire and broil the beefsteak and fry the bacon and eggs, and peel the potatoes and shell the peas and boil the coffee and make the toast; and to sit down and stuff it all in quick before it got cold and spoiled, and then to crumb the table and put the things in the ice-box and sweep the floor and wash and dry the dishes and fill the kettle and carry out the ashes and bring in more wood; and then hitch up the horse and drive to town to get more stuff from the butcher and the baker and the grocer and the druggist, and then hurry back home because it was time for the next meal. For a long time it was worse even than that, for we had a sick baby, and the doctor had laid out an elaborate schedule for him, which included such trifles as broiled chopped meat and chicken broth and gruel and cream six or eight times a day. We have gone through with this sort of thing for weeks and months and even years; and now, as I look back upon it, it seems to me a miracle that we ever missed committing suicide, as we so often thought of doing.

And now will you stop and reflect that there are five million farms in this country, and an even larger number of workmen's homes; and that in every one of them there is some wretched slave, shut up to toil in just such a treadmill, without hope of respite for life—the men spending all of their energies in earning food and the women in cooking it; and all for no purpose, save to supply occupation for an army of doctors and another army of dentists and another army of druggists and another army of those who manufacture and advertise and sell and transport patent medicines? I have an account of the drug industry of the city of Detroit, in which it is set forth that in that city alone there are manufactured nine billion pills a year. And now bring yourself to realize that every single one of those pills represents a meal which somebody ought not to have eaten—the appalling total of a hundred meals a year for each man, woman, and infant in the country!

I have come out from all that as from a charnel-house into the bright sunlight and fresh air. I am spending the winter in the South with my little boy. We have a big house, but we should no more know what to do with a servant than we should know what to do with a white rhinoceros if President Roosevelt should send us one from East Africa. We have a barrel of walnuts in the pantry, and one of pecans; a sack of figs and one of prunes and one of raisins; and once a week the grocer-boy brings a big bunch of bananas and a box of oranges and a basket of persimmons, and there we are. Three times every day we put some of these things into a bowl and pump water over them till they are fresh and shiny, and then carry them out on to the lawn; and there we spread a newspaper into which we throw the nut-shells and the banana-peelings; and when we are all through we chuck the paper into the stove and put the bowls back in the kitchen, and our housework is all done. We have no fires and no dirt, no smells and no grease, no soiled dishes and no ice-box, and no garbage-can and no medicine-chest.

#### HAS MONEY FOR MISSIONS, ANYHOW.

I have been the recipient of GLEANINGS for many years, and a constant reader of the Home papers and Notes of Travel. I have been for seventeen years a Methodist minister in the mission fields of South Dakota, with an average salary of \$300, and no missionary money. I have always labored to make the people ambitious to carry their own work and also contribute of their own means to the mission fund. My prairie circuit last year, consisting of twenty-six members, furnished \$40.00 for missions. I feel called on to make this report, for I esteem A. I. Root one of my very best friends.

Bijou Hills, S. D., Dec. 31.

R. N. KRATZ.

## POULTRY DEPARTMENT

By A. I. ROOT.

#### UTILITY AND BEAUTY; CAN THEY BE COMBINED?

*Mr. Root:*—In your poultry department for Dec. 15 the heading reads: "Is it eggs and meat we want, or is it fancy feathers and a good-looking chicken?" This implies that a combination of both qualities is impossible; further, the article advocates Leghorns or Leghorn crosses for eggs and meat; if so, why Leghorns? Surely you would omit the meat clause. A Leghorn broiler is possibly a fairly good meat proposition; but beyond the broiler stage it is well to leave them out.

It is also assumed that "Leghorn" expresses egg type. Why? It is hard to find absolute authority to substantiate such claim; but at the same time it is generally acknowledged that the Leghorn is entitled to that distinction—not that it lays more eggs, but that it produces them more economically, and, as a pullet, becomes a producer ahead of other types.

It is very hard for me to believe that fine feathers and excellent type would lessen egg production or carcass value; and I thoroughly believe that the best layers in the land will be found where the stock grades the highest. Certainly some fancy drones exist in every fancy flock; but surely some drones continue their useless lives in common flocks.

Is it not a fact that the most authentic reports of actual performance can be obtained only from fanciers and specialists? Is it not true that the fancier has the best of reasons for keeping track of individual performance? and does not the fancier set a higher value on performance when the eggs produced have a highly enhanced value than does the commercial poulterer who sells eggs by the dozen?

It would interest many of your readers could they assemble as one of a bunch of real cranks—I mean the kind that dilates on barring, penciling, under-color, etc., and then hear the trap-nest talk. You would soon learn that the laying quality was considered very important, and some of the records made for certain periods would make Ananias jealous of his laurels; but the fancier does not put egg production first; but at the same time that very important function is rated high, and an outstanding specimen from the fancy standpoint that is also a heavy layer is valued far beyond the reach of ordinary buyers. In fact, it is only the fancier who will pay a fancy price for a fancy performance.

I heard two fanciers offer \$2.00 apiece for every egg that one certain Barred Rock pullet would lay during the coming months of March and April. This was at the late Chicago show, and the offer was refused point blank, if that pullet turns out to be as good a layer as other Barred Rocks that I have owned; her owner turned down an offer of at least \$100 for her produce for two months. Suppose she had been a hen with an authentic record of 250 eggs for the preceding year, but she herself lacking in high-class breeding characteristics, do you think there would have been several buyers willing to take all her eggs at \$2.00 apiece? I don't. I know all the parties pertaining to the foregoing paragraph, or would not have mentioned the circumstance.

I have no wish to belittle the value of laying quality, but I here assert as my honest belief that fine feathers do not lessen the laying function, and that ordinary flocks are benefited by using high-class males; for it goes without argument that in the course of a few years the heaviest layers in a flock will have the greatest number of descendants.

Many flocks have been ruined by crossing; and advocating this method is dangerous for usually those who try it are the least capable of controlling it; and a fairly good flock may degenerate into dunghills very promptly.

All the American breeds and varieties combine utility with fine feathers, and some other classes do likewise; but Leghorn crosses are not likely to add any valuable feature to any of the popular breeds.

Sioux City, Iowa, Dec. 27. MATT. W. BALDWIN.

Thanks, friend B., for the facts you present and for your protest against haphazard crossing. I afterward thought better of my resolve on the spur of the moment, and my Leghorns have not been crossed. In a re-

cent talk with Chas. McClave, of New London, O., he informed me that all the great layers of recent date have come from high-scoring strains of fowls. The perusal of Kellerstrauss' new book has given me faith in the results of years of careful work in perfecting a strain.

#### WHY MR. ROOT LOST HIS LITTLE CHICKS.

In GLEANINGS for Feb. 1st Mr. Root gave his experience with rats and other animals killing his chicks, which was really as sad to me as it was for him.

I have found it best, when buying an article of any kind that was new to me, and I did not know a'bout the thing, to read the instructions thoroughly and follow them. Mr. Root, having bought a lampless brooder, did not put his 60 or 70 chicks into it for two weeks after hatching, which was most decidedly wrong. In this case he thinks a basket and a cheap burlap covering is better, thereby showing to me that he did not have any faith in a lampless brooder until the chicks were partly grown. And when he did change the chicks from the basket to the brooder it had to be a *forced* change, because it is not a chick's nature to change its location or roosting-place.

Now, if Mr. Root had taken "my word for it," and placed his chicks direct from the incubator to the brooder, and placed the brooder out in his yard, and closed the doors up tight for twelve to eighteen hours out of every twenty-four for at least three days, he would undoubtedly have had all his chicks now. The brooder is animal-proof when the doors are shut unless they gnaw through the material. Having placed the brooder in the yard, the "prowler" would have given Mr. Root warning of its presence long before the ten days were up, at the end of which time I recommend leaving the small door open for more air, and in the meantime the chicks would have learned that the brooder was their protection from storms; and when it rained it would have been Mr. Root's pleasure to see the chicks "put" for the brooder instead of trying to catch them under such difficulties.

The best way to catch chicks is with a broom. Take it in the right hand about half way down the handle, and circle it around over a chick, just heavy enough to stop its running, and then pick the chick up with the other hand. With a little practice Mr. Root will be able to pick up one hundred chicks in five minutes.

My advice to Mr. Root is to "try again;" follow the instructions, and be happy next time. I have learned to raise chickens "just nature's way"—Mr. Root may call it God's way. I am trying to impart my knowledge to others through my instructions; and when followed it will lead to a most satisfactory success.

Chicks are prey to cats, hawks, and a large number of animals. A great many animals will go through and under a fence—the cats and hawks, over it. A good watch-dog for night and a shotgun for daytime are about the best protection for a chicken-yard.

Aurora, Ill., Feb. 10.

V. W. CLOUGH.

But, my good friend, how about that incomplete "dooryard"? Surely \$2.50 is enough to pay for a dooryard 2½ feet square and 6 in. high (*thin lumber*), finished complete. Because this is a warm climate, I sent for the dooryard so the chicks could have good ventilation on hot nights; and when I saw it was netting only overhead I was, as I have said, a little fearful. I did read "directions" carefully, and the chicks had been in the brooder a week or more, and knew where to go. After I put on the netting *that you omitted*, the "night prowlers" tunneled clear under it and under the brooder, going under ground on one side and out the other in their frantic efforts to get the chicks. Thanks for your plan of catching chickens with a broom. I wonder if some woman didn't suggest the idea. A dog and a shotgun are probably all right; but while poultry netting, even small mesh, is so cheap, why not have your fowls, big

and little, where they can be locked up nights and still have such ample ventilation as T. B. Terry is writing about? It is worth something to me to know, when I go to sleep nights, that all my fowls, big and little, are *absolutely safe*. I know it is some trouble to go around and shut all the doors after they are "gone to roost," and then get up at "peep of dawn" and let them all out; but after a faithful trial I feel sure it is worth all it costs to make these frequent visits in getting acquainted with the chickens so you can be on familiar terms with them, aside from the security from prowlers.

#### DO HENS LAY IN THE SUMMER TIME IN FLORIDA?

When I was on the island I was told by the people there they seldom got eggs of any account in summer; and when I reached there in the middle of November, they said the hens had just started to lay. I have alluded to this matter before; and as a proof that that they do lay every month in the year, if properly cared for, I give below a report from my neighbor who took my fowls while I was in Ohio during the summer.

#### EGGS FROM A. I. ROOT'S HENS DURING THE SUMMER.

April, 1166; May, 834; June, 741; July, 683; August, 767; September, 578; October, 420. Average number of hens, about 65; average number of eggs per day, 24.

You will notice October was much the lowest on account of moulting; and, if you recall, when I arrived here in November I got very few eggs for some little time. Many of the above 65 are two years old, and a few *three years*.

#### FIRELESS BROODERS.

It is refreshing to note that so good an authority as *Poultry Record* has arrived at exactly the same conclusion I have already expressed in regard to fireless brooders and a brooder-house for the fireless brooder. Read the following:

For a hover for a fireless brooder I prefer a loose sagging blanket to slitted rags, as the chicks are apt to become tangled up in the rags or ravelings from them. With a sagging blanket there is no danger of this. Any one can make a fireless brooder. There are a great many patterns and some complicated affairs; but so far as I know they are no better than the simple patterns. I make mine out of cracker-boxes; pad the sides and have a warm sagging blanket attached to a frame that rests on cleats on the inside of the box. I have a pad or pillow stuffed with hay, feathers, or cotton which I lay over the frame holding the hover blanket to conserve the heat when the weather is cold. I have intake holes for fresh air near the bottom, and outlets above the blanket. It is a very simple affair, and can be made in a short time at a cost for material of from 25 to 50 cts. The brooders are so inexpensive that there is no necessity for crowding the chicks.

The expensive part of operating a fireless brooder is the coop in which it is placed. A brooder-house or colony-houses are necessary. The small low-down coops which we see recommended are not practical, in my opinion. I once used some of these coops, and every time I opened them the chicks would fly out; or when it was necessary to close them during a storm the chicks were in darkness. I then came to the conclusion that, to raise chicks with any kind of brooder, it is necessary to have it under shelter where the attendant can get in among the chicks.

# GLEANINGS IN BEE CULTURE

## EDITORIAL

By E. R. ROOT.

THE plan suggested by Mr. O. B. Metcalfe, one of the firm of Metcalfe & Parks, extensive honey-producers of New Mexico, for securing a wire to the end of a needle, seems as if it might be a good thing. We shall be glad to get reports from others who may be in position to try it.

### ATTENTION, OHIO BEE-KEEPERS!

OHIO bee-keepers, if they have not already done so, should write at once to their Senators and Representatives, urging them to support the Patterson foul-brood bill recently introduced in the Senate. There is every thing to show that the bill will pass both houses, and receive the signature of the Governor, *providing* Senators and Representatives are urged to vote for it by one or more of their constituents. It is up to you Ohio bee-keepers to write at once if you have not already done it. The full text of the proposed law was given on page 171 of our last issue.

### SPRAYING, AND THE RELATION OF BEES TO FRUIT.

By the time this journal reaches our readers, spraying will be in progress. In most States there are no laws against spraying at any time; but in the majority of cases, progressive fruit-growers do not spray until before and after blossoming time. They know that spraying destroys many of the delicate parts necessary to get good fruit, and that the time to do the work is before the blossoms come out and about a week after the petals—that is, the white bloom—have fallen off.

Of course, the mixtures of lime and sulphur washes and the oil emulsions to destroy the San Jose scale can not harm bees. It is the arsenites designed to kill the codling moth that do the mischief. Metcalfe & Parks, of Mesilla Park, New Mexico, lost last year very heavily because the fruit-growers in their vicinity insisted on spraying their trees when in bloom. All who are situated as Metcalfe & Parks are should begin a campaign of education. Secure bulletins from the experiment stations, mark them, and turn them over to the fruit-growers. F. A. Waugh, one of the best authorities on fruit culture in this country, and

author of a number of excellent books on fruit culture, advises against spraying while trees are in bloom. See what Mr. Waugh has to say in next issue.

Nature has designed that bees shall perform a very important work in pollinating fruit-trees. That, of course, means more and better fruit. Many varieties of fruit are sterile to their own pollen. This is especially true of some apples, pears, and plums. The wind, as the article in this issue shows, will carry the pollen but a short distance. Therefore it seems that nature designs that insects (and that means bees) shall perform the important work of cross-fertilization. Darwin, Fletcher, Waite, and others have shown conclusively that nature seems to abhor self-fertilization, and seeks the pollen of *other* trees and plants. This explains why many fruit-growers are asking bee-keepers to put colonies of bees in their orchards. They know that the presence of bees helps to secure more and better fruit.

### WINTERING AS REPORTED FROM DIFFERENT PARTS OF THE COUNTRY.

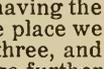

THE reports are very conflicting, sometimes even from the same locality. For instance, one of our correspondents from Nebraska reports heavy losses everywhere, while another one there says the bees never wintered better. As nearly as we can gather, winter losses are confined *mainly* to localities such as are found in Southern Ohio, Northern Tennessee, Southern Illinois, and along about that latitude. Further north, where the bees are mostly in double-walled hives, and were fed in the fall, there appears to be comparatively good wintering. In nearly all the cases of cellar wintering reports are favorable. In most of the Northern States where it has been very cold, and there has been a large amount of snow, the wintering has been good providing that bees have been well housed in double-walled hives well packed. In nearly all cases where they have been left in single-walled hives with honey-dew stores, the losses have been very heavy. In what is ordinarily understood as the Southern States, presumably the wintering has been good. The only danger in that part of the country is starvation.

### LOCATING AN APIARY.

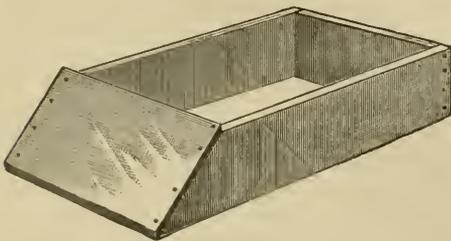

ABOUT the time this issue reaches many of our subscribers some of them will be locat-

ing their yards. A few suggestions at this time may not come amiss.

First and very important, do not put an apiary near a line fence, especially if that fence is or will be next to a cultivated field. It will be well for the bee-keeper to locate his bees as remotely as possible from his own cultivated fields; and if he owns a town lot he should put them clear at the back end of it, as far away from the highway as possible.

Generally speaking, hives should face the south; but there are times when it may be necessary to have the entrances face in different directions to avoid confusion on the part of the bees, especially if the hives are arranged on the group plan. For instance, we consider it poor policy to place four or five hives in a row, facing in the same direction. There is almost sure to be confusion, loss of queens, and danger of strong colonies drawing from the weaker ones. One can locate three hives in a group, all facing the same way; but we would not go beyond that number. If there are five hives in a group we advise the arrangement shown in the diagram below, the dot indicating the entrance. The three hives should  face the south, and the other two  east and west. We would advise having the groups irregular as to size. In one place we would put two hives, in another three, and in another five. Then we would go further and pick out distinguishing objects such as a clump of bushes, a little tree, or something of the sort that would differentiate one group from another. We regard it as very important to place the hives so that each entrance will have an individuality of its own. This is quite important when young bees and the young queen come out for the first time.

As we go over the country we find a good many bee-keepers locate their hives directly on the ground. Such a policy is destructive to the hive-bottom, and the hive is too low down to work over to advantage. We do not know of any thing better than a hive-stand made of rough lumber on the plan shown in the accompanying illustration. If

you do not wish to buy them of the dealer, go to your planing-mill and get the cheapest and poorest stuff you can find that will hold a nail. The front board should slope from the ground to the entrance. This is very important in the spring and fall of the year, and during the height of the honey-flow. While the lumber for this hive-stand is cheap, if properly nailed it will hold the hive proper off the ground for ten or even twenty

years. The bottom edges may rot, but the rotting will take place so slowly that it is inappreciable.

If the hives are arranged in groups, this bottom-board is rather expensive. In that case one could make an oblong frame, place the hive crosswise on it, then lean a board from the ground up to each entrance. Do not forget to give the bees a runway, for this will be found to be worth its cost.

The question now arises, "Shall we have shade?" This depends on locality. In hot climates shade is indispensable. The Arizona plan of shade running east and west is probably as good as any. In the north-temperate climates a little shade is an advantage; but too much is a detriment. Small shrubbery is about right. The shade of *old* apple-trees is a little too dense, while that of young trees, say four or five years old, is about right.

In some places shade-boards made of rough-sawn thin lumber projecting front and rear as well as on the sides of the hives would have to be used, possibly, during the hottest part of the season; but during very windy weather a 15-lb. stone or some other sort of weight is required to hold them on. For this reason we would prefer natural shade.

#### OUTDOOR WINTERING EXPERIMENTS AT MEDINA; GOOD RESULTS FROM THICK SYRUP FED LATE.

It will be remembered that last fall we packed our outdoor-wintered colonies in different ways. Some colonies had a large excess of honey-dew; others, honey-dew with syrup on top, and still others almost entirely sugar stores. Some of the colonies were fed early in the fall with a moderately thick syrup; others were fed very late with a very thick syrup, or as thick as the bees could take it.

Most colonies were under sealed covers, while some few were under absorbing cushions. The great majority were packed in double-walled chaff hives, and a few in single-walled hives were wrapped in paper winter cases and a few in wooden winter cases; other colonies on the weak order were put in the cellar in single-walled hives. For the total aggregate the percentage of loss was very light, not exceeding 3 per cent.

It will be remembered that last fall we had fears that the large amount of honey-dew that had been gathered all over the country would result in heavy winter mortality. While some reports show heavy losses, yet those losses have not been nearly as heavy as we expected.

At our south yard, where there was much honey-dew gathered, we expected the mortality to be heaviest, and it was. Five colonies died outright out of 75, and perhaps three dozen more were weak. Out of this number quite a few seemed to have dysentery rather badly. As nearly as we could ascertain, this dysentery was much more pronounced on honey-dew stores. Where a colony had been fed largely on sugar syrup,

even though fed late it came out in comparatively good condition, with very little loss.

At the Clark yard, where no honey-dew was gathered, and the bees were fed on very thick sugar syrup, there was no loss except two colonies that were very strong, and they starved. We had underestimated their strength, and consequently did not provide the necessary stores. All the other colonies of that yard came through sweet and clean. Their stores were made up of basswood and clover honey topped off with a little feeding of thick sugar syrup, along the last of November. It turned cold soon after, so that the bees could not cap these stores; and yet in spite of this the results were as above stated.

At the home yard of about 300 colonies, indoors and out, there were only two colonies that died, and that was through starvation. This was not because there were no stores in the hives, but because the clusters had moved over to one side; and on account of the long continued cold they used up all the stores on that side, and, apparently, not being able to get over to the other side of the hive, where there were stores, they starved. For the purpose of experiment some two and three frame nuclei were wintered outdoors under sealed covers. They all wintered well.

The bees at both the Home and Clark yards were in good condition—in fact, they were practically of the same stock. All the nervous and irritable bees, and all the off stock, were put into the south yard; and these odds and ends, so to speak, together with the poor quality of the stores, doubtless contributed to the comparatively poor wintering at that yard.

Bees at the north yard gathered considerable honey-dew. This was the yard where there were over 2000 queens reared last season. All the colonies were drawn on heavily for brood and bees. But the bees here wintered better than they did at the south yard, although they were not in as good condition as the bees in the two other yards. The heavy drain of queen-rearing, and scarcity of stores, doubtless accounted for this.

#### SEALED COVERS VS. ABSORBENTS.

There was very little difference to be noticed between colonies packed under sealed covers and those under absorbents. The difference, if any, Mr. Bain says, was in favor of the first mentioned. When it is remembered that we have tried these two forms of wintering side by side for a series of years, with the odds nearly always in favor of the sealed covers, the reader can naturally see why we champion that plan—at least for our locality. We have a suspicion that those who so loudly champion the absorbing-cushion plan of wintering may not have tested side by side the sealed-cover and absorbing-cushion plans; for if they were to do so for a series of years they might find the sealed cover simpler to handle, and during some seasons considerably in the lead so far as results are concerned.

#### PAPER WINTER CASES.

There was comparatively little difference between the paper-winter-case-packed colonies and those in double-walled chaff-packed hives. The difference, if any, however, was in favor of the latter. The greater the thickness of walls, and the better the packing material, the better the results. If the walls are very thick it renders the hive too expensive, and the difference in cost is not offset by the slight gain in the saving of bee life.

#### RECAPITULATION; THICK VS. A THIN SYRUP AND FEEDING LATE.

As the result of our experiments indoors and outdoors during this past severe winter, honey-dew stores have sustained their reputation to a great extent for being an inferior food for wintering, although the results are not as disastrous as might have been expected, judging from previous years.

Sugar syrup fed thick, even though late in the season, has again demonstrated its ability to bring bees through safely to spring. It is clearly proven that a thick sugar syrup is better than a thin one for winter feeding, and we are inclined to the opinion that late feeding of a thick syrup is not detrimental, as has been supposed, but even has its advantages. Slow feeding in the fall, with a thin syrup, exhausts the vitality of the bees, because they must drive out the excess of water, and this seems a severe drain on them at a time of year when their strength should be conserved. By giving the thick syrup, two and a half to one, comparatively late in the season, the bees are given the very best feed, even though they will not be able to invert it or cap it over. Feeding a large amount of thick syrup practically in one dose does not exhaust the vitality of a colony nor unduly excite it like repeated doses of thin syrup extended over a period of two or three weeks. While we advocate feeding early enough so that the bees can cap the stores, our experience seems to show that this is not essential. At one yard where our bees wintered so well it was so cold when we fed late last fall that the syrup was given hot. There were no fly days after that, and it stayed continuously cold until the fore part of March.

#### SIZE OF ENTRANCES.

Still another fact that was somewhat surprising was that those colonies having a wide-open entrance, one inch deep by the width of the hive, seemed to winter as well as those having a contracted entrance  $\frac{1}{4}$  inch deep by 8 inches. Our Mr. Bain, however, suggests that the snows were so deep all last winter that the entrance of all colonies, large and small, were closed from chilling drafts of air. During open winter we have found that wide-open entrances were too much of a good thing, and have, consequently, advised a limited contraction.

It seems to be proven again that, for our locality at least, sealed covers have the preference, as they make less trouble, and the bees under them winter perfectly. More we could not ask.

## STRAY STRAWS

BY DR. C. C. MILLER

WHY NOT make of cement those hive-stands of F. Greiner, p. 149?

MRS. J. W. BACON's plan, page 183, of running up to 12 or more brood-frames and then reducing to 8 when putting on supers, is excellent practice. We do it here by using two eight frame bodies.

J. E. CRANE, you're naughty to try to drive me out of bee-keeping, page 173, by saying I must locate bees where stones are not needed to keep covers from blowing off. No such location here. But with flat covers I never use stones except sometimes early when covers have been cracked open and it is too cold for glue to stick them on again.

NEVER BEFORE did I know a winter here when grass stayed green all the time from fall till growth started in spring. Clover shows up fine. But will it honey? as the Germans say. [Clover is fine here, and reports are favorable wherever it usually grows. Will it "honey"? We never knew of a year when it did not "honey" after a heavy snow.—ED.]

J. L. BYER, you ask me to mete out justice in that case, p. 192. The editor prefers that the subject shall "requiescat in pace;" but you come to the next Chicago convention and meet me at meat between sessions, and I'll mete out all the justice you want. It is just as easily settled as were lots of cases where two men had herds of cattle on the same wild land; and please remember that at present, so far as bees are concerned, all land is wild land.

MR. SIMMINS is a man for whose word I have great respect; but I am just a bit skeptical as to meal-feeding being as bad as he paints it, p. 178. I have fed many bushels of ground corn and oats in spring, and never knew any bad results from it. Still, there is the possibility that I am, as he says, "not too observant." [This is a problem that will vary somewhat according to locality. There is danger of coaxing the bees out too early. Nature does not usually furnish natural pollen before the bees ought to have it. Man very often tampers with nature, disarranging her plans, with the result that trouble follows. Notwithstanding, we think there are times when bees may and should be given artificial pollen. As many noted last spring, considerable brood died because of improperly balanced ration—that is, a lack of the nitrogenous element in their food. Of course we have no positive evidence that the brood died from this cause; but the circumstantial evidence was very strong.—ED.]

VIRGIL WEAVER, much obliged for promise, p. 197, of a crop this year; but how am I to tell whether winter has nothing to do with it? The winter of 1908 was open; and although plants could be seen quite early, their roots must have been hurt, for later on they

disappeared and few plants were to be seen, to say nothing of blossoms, so of course there could be no honey crop in 1909, and it looks as if winter had killed the plants. The winter of 1909 had such a snow-blanket as I never knew before; plants look superb; and if there's a bumper crop one can hardly blame that snow-blanket for putting in a bill of charges for winter protection. [Mr. Weaver has fairly earned a reputation for being a good prophet. His predictions for the last three or four years have come very near being true. He may be mistaken in some of his conclusions, but in the main he seems to have discovered some conditions that are favorable and unfavorable to a clover yield.—ED.]

CAN IT BE that locality makes a big difference about the kind of day when bees should be taken out of the cellar? In this locality a warm sunny day is always chosen for taking out bees; and the ill results mentioned, p. 195, do not follow. The entrances are immediately closed up to a square inch or less, and that probably makes a difference about drifting. If a colony is *quietly* placed upon its stand when warm enough to fly, why should it fly out any differently from what it would if it had been on its stand for a week? An important item is that the cellar must be wide open all night before taking out. If I should take them out on a cold cloudy day there might come severe cold for a week or more, when they would be very much better off in the cellar.

P. S.—Since writing the above I have read R. F. Holtermann's "drifting" article, page 196. He thinks the principal cause is "excitement on the part of the bees so that they do not mark their location as they leave the hive," and he also thinks "the rapid changes of conditions from inside atmosphere to the outside increase the excitement of the first fly." You will see that I provide for both these contingences. By having the cellar wide open the previous night there is little change upon going to the outside atmosphere, and I think the contracted entrance does much to make them mark their location. [It may be that giving bees fresh air the night before taking them out of the cellar may to a great extent overcome the excitement that would take place under other conditions when set out. In our locality we can be reasonably sure of favorable weather on a day following. The United States weather reports are fairly reliable. Let us suppose that to-day it is a little too cool for the bees to fly. The weather report shows that it will be warm and balmy tomorrow, with probably a clear sky, which means sunshine, of course. We set the bees out toward night. It is a little cool during the night; and as the cluster gradually unfolds the next morning the bees find their way to the entrance; and when the temperature is right they will come out gradually—not with a pell-mell rush. As the hives are all out, we avoid some of that "drifting" of which we have been reading, and ere long the bees quiet down to normal.—ED.]

## BEE-KEEPING AMONG THE ROCKIES.

BY WESLEY FOSTER, BOULDER, COL.

### WINTER VENTILATION.

If bees have a large winter entrance they are more apt to come through in better shape than if the entrance were contracted. If mice are troublesome they may be kept out of the hives by using wire screen three mesh to the inch over the entrance. The value of abundant ventilation during the winter is better known now among western bee-keepers than a few years ago. The contraction of the entrance is still thought to be essential by many; but some of the most successful ones have had some experiences that point the other way.

### THE SNOW ON THE RANGE AND ITS EFFECT ON THE WATER SUPPLY.

Government reports from the mountains show that the fall of snow so far is below the average, and that there will be less water for irrigation than last year unless a great deal falls from now on. The warm days in the winter, which aid in settling and packing the snow into ice sheets on the high levels of the ranges, have been numerous this winter—at least they came at times when there was snow to be settled and packed. The report says there is considerable soft snow in the timber on the lower levels and foot hills. This condition of snowfall is general throughout the mountains of Colorado.

### SHIPPING COMB HONEY; FREIGHT CLASSIFICATIONS, ETC.

A shipment of comb honey was recently made from a distance of several hundred miles into Denver. The shipper did not know that the glass fronts should be protected with wood strips so the shipment would take the lowest possible freight rate, which is the first-class rate in less than carload lots. The first-class rate is \$1.70 between this point and Denver; and where the glass fronts are not protected the rate is double first class; so it cost this bee-keeper \$3.40 a hundred to ship his honey to market. By tacking a little strip of wood over the glass, 45 cents a case in freight would have been saved.

This ruling of the railroads in regard to comb honey in glass-front cases is unjust I think; for where the glass shows the contents of the case it is much more likely to be carefully handled. A lot of single-tier cases of honey with wood slide in place of glass came through in very bad shape, practically all of it mashed and broken. The freight men thought it was cheese or butter, no doubt.

These instances show that bee-keepers can not be too well posted on freight rates, classifications, and the proper way to ship honey.

If the freight agent in the first case spoken of had been looking out for the best interests of his company's customers he would have told the bee-keeper how to secure the lowest possible rate.

### COMB-HONEY CASES WITHOUT GLASS.

This whole question of glass cases or no glass has reference to producing sections of the country and the distant markets. Fruit and honey have met much the same conditions in seeking a market. Twenty years ago the bulk of the fruit crop was produced in the Eastern States, where the most of it found ready sale in nearby markets. The battle for markets was not severe, and extra bids were not made for trade. With the commercial orchards of the West, where markets were two thousand miles distant, the sales demanded the packing of only the choicest sound fruit, for the inferior produce would spoil before the market could be reached. The profitable following of fruit culture at once depended on allowing only the best fruit to mature on the trees so all the crop would be fit to ship. Then when the Western growers found out their only hope was in quality (they could not sell average fruit in competition with Eastern fruit), they had to raise a better article, put it up more attractively, and get a higher price. The covering of the edge of a box of dried peaches with lace paper has added 10 to 15 cts. to the price received.

This is the state of affairs in the honey market. Western honey has to be whiter, and more attractively put up in double-tier shipping-cases, to find a sale in the Eastern markets. But those markets now want the goods the way we put them up, with one fourth of the case exposed to the glass front.

Mr. Scholl objects very much to the Colorado methods of producing honey; but we could not produce comb honey in bulk and ship into Texas to compete with his product. The cost of shipment would prohibit, and then we should have to sell it as cheap as he sells his or not find a market. But we can sell our comb honey right in Mr. Scholl's Texas markets because we are supplying a demand Mr. Scholl does not meet. We cater to a trade Mr. Scholl considers unprofitable. It may be, in comparison with his bulk-honey business, but it is the only way we can dispose of our Colorado crop. I think we get much more per pound than Mr. Scholl, though it costs us much more to produce it.

Cars of comb honey have been shipped out of Colorado by the score at \$3.00 net per case to the producer, and I know of one car that brought \$3.15 per case of 24 sections. For the actual weight of honey in a case, that would be at least 16 cts. per lb.

I do not doubt that Mr. Scholl can make more money with bulk honey in his location and relation to markets; but I think Colorado and other Western bee-keepers do better to produce a white comb or extracted honey.

## NOTES FROM CANADA

BY R. F. HOLTERMANN.

### WINTER LOSSES.

At this time of writing, March 8, bees in this section of country, if outside, have had a splendid fly. So far as I can judge, bees properly prepared and wintered outside have wintered well. On Saturday, March 5, the weather was so mild the bees were working on hyacinth and other blossoms offered for sale on the Brantford market square.

### IS HONEY-DEW AN EXCRETION?

Observations covering many years and sections of the country convince me that honey-dew may be an excretion from plant-lice or that it may be given off by the leaves themselves. It may be possible to prove the above; but I pity any one who attempts to prove that it never is an excretion. In my estimation, not much damage can be done to the honey-dew industry. It speaks for itself.

### ARTIFICIAL POLLEN.

Jacob Alpaugh recommends peameal or "Brose" as a substitute for pollen, and advises mixing it with chopped oats or bran, feeding it in a sheltered place near the apiary, setting the trays out in the morning, and taking them in or covering them in the evening so the dew will not wet the mixture. He recommends either putting a little honey here and there on the artificial pollen to entice the bees, or putting some on the end of a stick, collect bees on the end of this stick from the entrance of a hive, and then carry the bees to the pollen on the stick, in this way introducing the bees to the pollen.

### WHEN THE SWARMING TENDENCY IS GREATEST.

Page 138, March 1, Wesley Foster says: "In this country I know the control of swarming hangs around a few days after the lower hive is well filled before we get the bees fully convinced that supers are the next on the program, and not swarming." The above is a very important point in this country. I consider that, when the time indicated is timed over, there is not much danger from swarming until the supers become crowded. A large entrance and shade are, however, no mean factors in preventing swarming.

### KEEPING HONEY FROM GRANULATING.

On page 134, March 1, the editor states, "Apparently, then, a very cold temperature or a very warm temperature is less favorable to granulation than any point between." This is just my experience. To quite an extent the result from these two extremes is the same. In the former, granules show no tendency to form (may I so express it?); in the latter the honey is so thick the particles can not move, and the process is retarded. In this latter case, however, I believe a microscopic examination would reveal many fine grains.

The provincial apiarist has sent out the following advice, which will commend itself to bee-keepers generally:

I understand from our inspector's reports that you have had, within recent years, foul brood in your apiary. If this is the case you should be particularly careful to prevent robbing during the warm days between now and summer. All hives where bees have died must be taken indoors, away from all possible robbing. It is not enough to close them, because robbers will often gain an entrance when least expected. All entrances of live colonies should be made quite small, especially where the bees are weak in numbers.

Use every precaution and great watchfulness to prevent robbing. Do not under any circumstances leave combs of honey out for the bees to clean up. Any honey you have is likely to contain germs which would scatter disease in your healthy colonies. On account of prevalence of disease in unexpected places throughout the province it is neverwise to feed honey to bees; and where disease is known to exist it is the worst of folly.

I hope you understand fully the symptoms and cure of foul brood. If so, you can be your own doctor, as the inspector's time is fully occupied with those who do not understand the disease. If not, drop me a card, and a bulletin with description, and full instructions will be sent you.

### LECTURING IN CANADA.

On page 42 the *British Bee Journal* contains the following:

I am an old English country bee-keeper, and have settled out here in British Columbia. I find the American system of bee-keeping is the only one practiced; and, having learned all there is to be known about it, I keep my opinion that it is not to be compared with our British method of manipulation. We enjoy very long summers here, and the climate is favorable for bees; but there does not seem to be any one except novices in the bee-business, and some have been very successful, so I have no fear of my results. I am an all-Britisher if possible, and shall push the old-country appliances as soon as I can fix up my depot and get a good home firm to represent. By profession I am a watchmaker; but out here things are not so finely defined, and it is not unusual to change one's trade. What books would you recommend to one who intends to make bees a leading line as a lecturer, for instance?

Victoria, B. C.

E. C. APLEBY.

Many English complain that they are not properly treated by Canadians when they come to this country. Let me point out that the above remark indicates clearly a spirit that Canadians say is altogether too prevalent among the English when they come to Canada; and the few or many, as the case may be, who manifest this spirit make the position difficult for those among the English (and I believe of the latter there are many) who have no such exalted view of their own attainments.

As far as the position of lecturer is concerned, there is no such opening in this country; and if there were a lecturer going abroad in such a spirit he would have to become his own employee, advertiser, audience, etc.

I have read the *British Bee Journal* with profit for years, as also German and French journals, and these papers can be read with profit by bee-keepers on this continent; yet what little I know of "the American system of bee-keeping," and particularly in its *apian* appliances, has a foremost place with me. I believe we have been ready to embody every good invention, such as the honey-extractor, comb foundation, etc., into our system, and therefore we have never assumed a position of *knowing it all*.

## CONVERSATIONS WITH DOOLITTLE

AT BORODINO, NEW YORK.

### WHAT CONSTITUTES A GOOD QUEEN?

"I have read your Conversation, October 15, and I want to know how you raise *good* queens so late in the season."

"How do you raise good queens at any time of the year, Mr. Van Deman, or in mid-summer, when a good yield of nectar is on?"

"That is very simple. I let the bees do it."

"Sure. And the bees do it in the fall. It is just as simple the first half of September, with feed and a little manipulation, as it is the first half of June, in this locality. In fact, the conditions during the former are equally propitious with the latter, for the first half of June gives us a dearth of nectar and more fluctuating weather than does September. But in either case, by feeding and stirring the bees up they are brought into as nearly the same condition at these times as are your bees in mid-summer when you just let the bees raise the queens themselves. In June the bees are more active than they are in September, when, as a rule, the excitement brought about by feeding is all that is necessary to put them in the same condition they are when a good flow of nectar is on. But in September the bees are not so active; and to bring them into the condition to raise good queens, after feeding for two days the queen is taken away from this colony (which should always be the strongest in the apiary), and the next day the bees are caused to fill themselves with honey by drumming on the hive, when four-fifths of them are shaken into an empty hive or box, the sides of which are covered with wire cloth. They are kept in this box from 9 A.M. to 2 P.M. Then all but the sealed brood which the colony contained is taken away, a frame of prepared cell cups given, and the bees returned from the box. During this five hours of being boxed, both the few bees left in the hive, and especially those in the box, come to realize fully that they need a queen, and need it fully as bad as in natural-swarmling time, which works them up to as much activity as is possible at any time of the year. This, with the continued feeding, brings out an extra-fine batch of queen cells from which emerge as fine queens as you ever set eyes on. However, with the exception of early spring and in the fall, our queens are reared in upper stories over a queen-excluder. See 'Scientific Queen-rearing.'"

"Now how about the drones?"

"Near the close of the drone-brood season, all the brood of that persuasion is taken from the three or four colonies having the best drone mothers at their head, and this brood massed in a strong queenless colony which is kept very strong by giving it an upper story, into which frames of emerging brood are inserted as often as is necessary to keep up the required strength. When

our September-reared queens are ready to mate this hive is looked over, and all the under-sized drones, and those apparently defective as to wing power, shape, or otherwise not what we would like, are killed off, when this colony is regularly fed between 12 and 1 o'clock each day, which causes an activity of these drones much above normal. In this way we get queens equal to those reared at any time, and, as all other drones, or at least the most of them, are now killed off, we get all of these queens mated to what has been termed 'hand-picked' stock."

"Do you select your breeders from these?"

"Very many of them."

"What constitutes a good breeder?"

"As a rule, we prefer a perfectly developed queen of about medium size. We have found that queens of abnormal size, or those much under size, are not equal to those which are about normal. Aside from size and perfect development, we next ascertain how her eggs are laid. If scattered about in the combs with missing cells here and there, together with some stuck on the sides of the cells, she can not be classed as a good breeder. Now, understand, this is when she has a hive of empty combs before her, as any queen has, as a rule, when she first begins to lay. If there is brood emerging here and there in the hive, any queen will scatter her eggs about among this brood, no matter how good she is. Then when her brood emerges from the cells and gets straightened up, say three days after they begin to emerge, these bees should be of normal size and show the regulation markings, while her queen progeny should be of the kind as to development, size, etc., as was the mother."

"There seems to be no standard as to what constitutes a pure queen of any race."

"I fear you have not read the many good books on bee-keeping. Nearly all of the books like the A B C and X Y Z of Bee Culture, Langstroth, Quinby, etc., treat on these things, and I would refer you to them."

"All right. But what is the size of a colony that can be called strong in the spring, say when the first pollen comes?"

"At a New York State bee-keepers' convention, some 25 years ago, this same question came up, and a committee was appointed to report on it. As my memory serves me, that committee told us that any colony which, on the first of May, in an average season, on a morning so cold that there was a frost, showed a cluster of bees between seven combs, or what is known as a six-space cluster, could be considered a good colony of bees, as such colonies would give better results at the end of the season, other things being equal, than colonies showing either more or fewer spaces occupied. And as I remember it, the sense of that convention was that the five-space cluster was preferred to any colony occupying from eight to ten spaces, or what would be considered an extra-strong colony at that time of the year. Years of experience has told me that the report of that committee was a wise one for a latitude ranging between 40 and 45 north."

## GENERAL CORRESPONDENCE

### LIQUEFYING CANDIED HONEY ON A LARGE SCALE.

#### Some Objections to the Solar Method of Treating Honey to Prevent Granulation.

BY O. B. METCALFE.

On p. 769, Dec. 15, Mr. H. R. Boardman describes his method of treating honey to the sun's rays to prevent its granulating. Now that some one else has mentioned it I have noted several times that honey heated by sunlight does not granulate quickly if at all. Season before last we had some 25 cases of honey in quart jars that candied before we could sell it. As an experiment I melted up some five or six cases of it in the sun extractor; and although several jars lay around for months it never candied again. I took notice of this fact, but thought it no doubt due to its getting too hot, for it came out of the sun extractor quite dark, and tasted badly "cooked."

Besides this experience, some five or six 1-lb. jars of candied extracted honey were set out on the sunny side of one of our honey-houses last spring. The sun liquefied the honey, and I remember that it remained so until the time I left home in the fall, but that also seemed to have been heated rather too much. Now I want to know how much the sun heats Mr. Boardman's honey, and how long he exposes it to the sun.

There is, perhaps, no question which more vitally concerns a New Mexico bee-keeper than the granulation of honey, and no place where bee-keepers could better give it the sun treatment if proven effectual.

C. W. Rever, in the same issue, p. 771, expresses his hopes of a fireless heater which will use the sun's heat for melting honey on a large scale. I have given this matter considerable thought, and have used the sun extractor to melt up a great deal of candied honey by emptying it into the trays of the extractors just as though it were cappings; however, I always melt up just some odd batch of honey in this way, such as a tub or small settling-tank full which has candied before it would settle or before we got it drawn off; and I did it with the understanding that it would get too hot and turn dark to sell as No. 1. In tin cans the result is even worse, for the melted honey can not run down out of the sunlight; but the unmelted chunk settles to the bottom, where it keeps cool longest, while the melted portion, which is already hot enough, is nearest the sun's heat, and gets hotter and hotter.

Heating by fire has the obvious advantage that the heat may be applied to a large bulk for as long a period as it takes to do the work, and *at the bottom*, where the unmelted chunk rests; or the honey may be stirred to

prevent its getting overheated in one place while unmelted in another.

One other point against melting honey in the sun extractor, which I noted, was that it would not quite *all* melt. A thin scale of sugar, which resembled rock candy, would settle to the bottom of the jar, and remain so, no matter if I left it for several days, while the slumgum in another part of the same sun extractor would register over 212° F. all through the hot part of the day.

Right here I wish to advise any bee-keeper who attempts the melting of a 35,000-lb. car of honey to make extensive preparations first for doing so. A year ago last fall, with my Mexican boy to help, I set about such a task. The first thing I did was to get enough galvanized iron to make a heater which would hold 27 60-lb. cans of honey, and take cordwood in the fire-box; and now as I think over that experience I believe that still better advice to my brother bee-keepers would be, "Don't let as much as a carload of honey candy on your hands unless you mean to bottle it yourself or sell it granulated." A carload of it candied hard is a big, cold, unrelenting mass.

#### THE CAUSE OF THE FINE SPECKS IN MR. BYER'S HONEY; HOT WAX AND HONEY SHOULD NOT BE STIRRED.

I am wondering if Mr. Byer, p. 779, stirred that honey in the capping melter. Season before last we were so late with our last extracting that the sun extractors would not melt the cappings; so I set to work to handle them by artificial heat. I made a heater which held 400 lbs., and dumped in the cappings as fast as they melted up. That worked well, for the next morning I had a lot of clear but well-cooked honey in the bottom; next a layer of slumgum, and on top a nice cake of yellow wax; but the honey was too dark and the process too slow, so I emptied the heater, fired up again, and filled in the cappings by the tubful; took a garden-hoe, and, standing over the melter, stirred all the time to keep the mass at an even temperature, meanwhile adding more cappings until the melter was full. I turned up the gasoline flames under it, and stirred constantly until the mixture reached about 160°F., then turned out the fires and left it to settle. Next morning I expected, of course, to have a fine cake of wax on top, a layer of slumgum, and in the bottom some good honey; but to my surprise, there was, instead of wax on top, a light sticky spongy substance. I drew off some honey from the bottom; but instead of being clear and nice, as I expected, it was cloudy; and upon close examination it was found to have tiny particles of wax all through it, even at the very bottom of the tank. I said to myself, "Well, I'll have to strain you!" but this I could not do, for it instantly clogged the strainer. Then I heated it so it would run through the strainer all right, and again left it to settle. The next day I found the same proposition. While hot, the wax, of course, went through the strainer, as I had finally seen it was doing the day before. I decided to give it

longer time to settle; but, alas! it never did settle so I could draw off clear honey from the bottom. My conclusion was that, if hot wax and hot honey are well stirred together, and if it is *thick* honey, the tiny globules of wax will not rise before the honey cools; and once it cools they will hardly rise at all; and it may candy before it will settle. It may be that the "veterans" know this; but I did not, and I am now wondering if it does not explain the specks which appeared like grains of pollen on the tops of Mr. Byer's honey-pails.

Mesilla Park, N. M.

[We have seen considerable of Mr. Boardman's honey; and, as we now recall, the color, body, and quality were the equal of any clover extracted we ever saw. Certainly the color could not be in any way considered darkened in the least.

There are a couple of conditions that may be considered as possibly influencing the color of your honey. First, you have a much hotter climate; and the presumption is that the heat inside of your sun extractors is much higher than would be the heat inside of Mr. Boardman's. But the most important factor is that you liquefy honey that has been actually candied solid in the sun extractor, and the long-continued high temperature required to bring it to a liquid condition would necessarily affect its color. Mr. Boardman does not, as we understand it, allow his honey to candy, but treats it *before* it candies, as explained in his article on page 768, Dec. 15, last year. In doing this his honey is not subjected to so long-continued a heat. We would infer, then, that the sun's rays, when applied no more than enough to arrest granulation in liquid honey, would not necessarily affect its color, although there is a bare possibility that alfalfa might be more susceptible to the actinic rays than ordinary clover or basswood. It is true that Mr. Boardman, in his earlier experiments, liquefied granulated honey; but his scheme seems to be confined to *liquid* honey.

It would seem to be very clear from your experience that candied honey can not be as satisfactorily liquefied by sun heat as by artificial. If we remember correctly, Mr. R. C. Aikin, of Loveland, Colorado, experienced somewhat the same difficulty in rendering up combs in his solars. He found that the honey and the wax on the top were overheated, while the slumgum beneath was only partially melted. To overcome this difficulty he applied artificial heat on the under side to the pan of the solar extractor, thus getting heat from above and below. This might eliminate a part of your trouble, although it would be our opinion, if artificial heat is to be used at all, that the increased cost from using the sun's rays would more than offset the slight advantage.

If any other correspondent has had the extensive experience of Mr. Metcalfe in liquefying candied honey by sun heat, we have never heard from him. Certainly his experiment was conducted on a sufficiently large

scale to justify the conclusion that solar heat is not satisfactory for melting up granulated honey.—ED.]

## BEE AS ROBBERS OF FLOWERS.

BY JOHN H. LOVELL.

Dr. Miller's wide range of information and genial humor render his page of notes most valuable and entertaining. *Apropos* of his remark on the absence of nectar from roses, while I certainly do not wish to be censorious, for we are all fallible enough, still I think that popular writers on the honey-bee should be more accurate in their statements. For example, a well-known writer of children's stories not long ago told in the *Ladies' Home Journal* of a bee that gathered honey and wax all through the long summer months. With a little effort the proper source of wax might easily have been learned.

Now as to the question, "Why do bees seek to enter the young buds of roses?" Perhaps a brief inquiry as to the behavior of bees (bumble-bees as well as honey-bees) toward flower-buds in general will be helpful.

The fly-honeysuckle, or *Lonicera ciliata*, is a graceful slender shrub which blooms in our rocky northern woodlands during the last weeks of May. The flower-stalk bears at its summit two pendulous, yellowish-green flowers, which are half an inch in length and tubular in form. The nectar is secreted and lodged at the base of this tube, where it can be readily reached by the long tongues of bumble-bees, by which chiefly this species is pollinated, though it is also visited by butterflies. But the female, or queen of *Bombus consimilis*, instead of waiting for the flower to expand often bites a hole through the bud. Sometimes the perforation is near the apex of the bud, but usually it is near the base of the tube, and in one instance I found the corolla nearly circumsised, and held by only a few threads.

Bees also puncture at the apex (usually on the under side) the buds of the common skullcap, or *Scutellaria galericulata*, even when they are quite immature. The flowers are labiate, or lipped, and in two instances I observed a narrow slit on the upper side of the corolla tube, and in a third case the whole upper portion of the tube was cut away, leaving the lips suspended by a mere thread. The buds and hollow tubular nectaries of many other flowers are robbed by bees in the same way. Let us go out into the field and observe how bees puncture the nectaries of two or three different kinds of flowers.

The familiar "touch-me-not" (*Impatiens fulva*) has its brown-spotted orange blossoms shaped like a horn-of-plenty with the spur inflexed or bent inward beneath it. This spur contains the nectar. The flower is suspended horizontally with the anthers and stigma lying upon its upper side, so that, when a bee enters the dilated corolla-sac, its back is dusted with pollen, which it carries away to another flower. While the spurs

may often be found intact, they are frequently punctured by bees. August 10 I examined a large number of flowers, but none of the nectaries were perforated, and they were visited in the legitimate way by *Bombus consimilis*, which made from seven to twelve visits per minute. The thorax of the bee was plentifully covered with pollen. From August 23 to 27 I found hundreds of the flowers perforated, and both bumble-bees and honey-bees stealing the nectar. A honey-bee was watched during 25 successive visits, and in no instance did it make even a pretense of visiting the flower in the normal way; but in every case it swung itself beneath it, got astride the spur, and began sucking the nectar. The number of visits per minute was about ten. Both the honey-bee and *Bombus terricola* were observed in the act of puncturing the nectary. The maxillæ alone were employed, and were moved slowly back and forth for the purpose of piercing the tissue. The perforation is usually 3—4 mm. from the end of the spur, which is 10—11 mm. long. Sometimes there is one, sometimes several openings, or there may be a slit 3 mm. long.

If, after the manner of certain plants famous in myth and story, the *Impatiens* (fitly in this respect called "touch-me-not") could speak, what a protest it would utter! For unknown centuries it has been building up its flower edifices only at last to find its work in danger of being rendered worse than useless by a change in the habits of its bee visitors. It should, however, also be stated that the flowers are frequently visited by humming-birds, and I have also seen another smaller species of bee enter the flower in search of pollen. Small beetles and spiders occasionally seek shelter in the sac, and various flies are attracted to the outside by the bright colors.

The columbines in my garden secrete nectar very plentifully. If a flower of the white variety be held so the light will shine through its translucent tissue, the nectar may be seen filling a tenth of an inch of the hollow spurs or nectaries. Both the purple and white varieties are punctured by bees. Mueller observed a bumble-bee, after licking the calyx in a fruitless endeavor to obtain the honey, bite a hole in the spur; and afterward it punctured the flowers visited, without any preliminary delay. I have observed three distinct incisions, one above the other, on a petal of this plant. The first was over half an inch from the tip of the spur, well up on the expanded part of the tube; the second was much lower down, and the third still nearer the tip. Apparently the upper puncture was too far distant to permit the tongue of the bee reaching the nectar; and to rectify this mistake the other holes were made lower down.

The flowers of the scarlet runner are very attractive to bees. August 14, in my garden the vines were in full bloom and were a blaze of glory. Honey-bees and bumble-bees were constantly coming and going, but not one of them entered the flower in the normal way.

There was a hole on the under side of every nectary; and, what was a little singular, they were all on the left-hand side. The bees went directly to these holes, out of which they easily sucked the nectar. More than 300 species of flowers are known in which bees bite holes, and which they rob of their nectar, and several of these often fail to produce seed. Both the mandibles and maxillæ are used for this purpose—the former for biting, the latter for piercing. If there are two small punctures side by side, they were made by the mandibles; but if a narrow slit, by the maxillæ. A few of the more common forms robbed by bees, besides those already mentioned, are the red clover, locust, *Dicentra corydalis*, dead nettle, larkspur, acornite, and vetch.

We are now in a position to answer Dr. Miller's question. Bees bite holes in many buds because the petals are united by their edges into tubes or bells, and they can not gain access to the interior of the flower in any other way. Their object is to find nectar before the flower opens. But in the rose all the petals are separate and distinct, and essentially alike. There is no occasion to puncture them. The bee gains an entrance to the flower by pushing its way between the petals of the growing bud. It is, no doubt, looking for nectar. Of course it does not then know that roses are nectarless; for if it is early in the season it has never before seen a rose. But bees very quickly learn from experience that the roses contain only pollen, and ever after they remember it. The ability of the bee to learn from experience is well illustrated by their behavior toward buckwheat blossoms, on which they work in the morning but not in the afternoon. So, too, they do not visit the gaudy, nectarless exotics of cultivation, for they have learned from experience that their time would be wasted. The mental attributes of the honey-bee are far too high to permit its flying in a mechanical way indefinitely to a flower from which it gains no advantage.

Waldoboro, Maine.

[The honey-bee is not provided with cutting-jaws like the wasp and beetles. At one time it was supposed that honey-bees could cut through flower-tubes; but some of our best authorities doubt this. The holes found near the nectaries of the flowers could easily be made by other insects provided with cutting-jaws. Unless you actually saw honey-bees do *all* of the cutting from start to finish on the touch-me-not, we should be inclined to the belief that other insects had already been there before, started the job, or made a minute hole which honey-bees, coming on later, could enlarge. We have proved this was the case when the charge was made that bees punctured grapes. We found that a small bird started the holes, and that, later on, bees came on and made the holes larger. In the case of the touch-me-not, "small beetles," and "spiders," both provided with cutting-jaws, and both of which you found on the flowers that were cut, might be the real culprits.—ED.]

## TREATISE ON POLLINATION OF APPLE-BLOSSOMS.

BY C. I. LEWIS AND C. C. VINCENT,  
of Oregon Agricultural College Experiment Station,  
Corvallis, Oregon.

[We take pleasure in presenting the following article from *Better Fruit*, on the subject of fruit-blossom fertilization, as it is of special interest to the majority of our readers at this time. Being written from the standpoint of the fruit-grower it is, of course, absolutely without prejudice in favor of the bees.—ED.]

It was not until the close of the last decade that the significance of pollination of apple and pear blossoms came into prominence. Through the efforts of M. B. Waite, in the United States Department of Agriculture, intelligent light was thrown upon this important question.

As far back as 1793 the importance of insects in pollination was impressed upon the minds of many investigators; and Mr. Sprengel, a German writer, published a book entitled, "The Secret of Nature in the Form and Fertilization of Flowers Discovered," which proved to be an effective stimulus for further work upon this interesting study. 

PLATE I.—FIRST STEP IN EMASCULATION

While Sprengel's work was practically forgotten, other investigators were making acute observations on the cross-fertilization of flowers, which completely overthrew the theory advanced by Sprengel, of the independent creation of species. Not long after Sprengel's book appeared, Andrew Knight carried on some very interesting experiments on the cross and self fertilization of the pea, and arrived at the conclusion that in no plant does self-fertilization occur for an unlimited number of generations.

But it was not until after the appearance of Darwin's "Origin of Species" that Knight's theory was emphasized as a general law of nature. At this time the real value of Sprengel's work was realized, and his discoveries opened up new paths for investigation, especially along the lines which were to determine the forms of flowers.

In Darwin's "Origin of Species" cross-fertilization was emphasized; but no special significance was attached to this discovery until the appearance of his second work, entitled "Various Contrivances by which British and Foreign Orchids are Fertilized by

PLATE II.—REMOVING THE PETALS

Insects." When summing up his work he states, "Nature abhors perpetual self-fertilization." Not content with these results, he explored new lines of investigation, and from careful observations noted differences in the action of pollen on the same and another flower. Darwin's work, "Variation of Animals and Plants under Domestication," suggests many interesting lines of original research work, and from these suggestions experimenters have branched out into new fields of investigation.

It was largely through the efforts of Darwin that Waite carried out the experiments outlined in his bulletin, "The Pollination of Pear Blossoms." Since then many investigators, such as F. A. Waugh, S. A. Beach, C. P. Close, M. M. Munson, S. W. Fletcher, U. P. Hedrick, and many others from the agricultural colleges in the United States, have worked on pollination problems. Likewise H. Mueller-Turgau, O. Kirchner, and Dr. Ewert, of Europe, have also carried on many investigations and experiments on this subject. The many reports sent into this station from various parts of our State, complaining of the lack of setting of fruit, have led to investigations on this problem by this department, some of which are reported in this bulletin.

### METHOD OF EMASCULATION.

Any one contemplating the carrying-on of pollination experiments must have a thorough knowledge of the parts of a flower before a high degree of success can be ob-

PLATE III.—REMOVING THE STAMENS

PLATE IV.—APPLYING POLLEN TO THE PISTILS

tained. Next, it is necessary to learn the operation of emasculating, which consists in removing the anthers from the flower. The object of this process is to prevent self-pollination. To remove these anthers in the best possible way is a serious question with many investigators. At this station the writers have received excellent results by the use of the method outlined below, and have made from six hundred to one thousand emasculations per day. In carrying on work of this nature, rapidity as well as efficiency must be sought.

*Method.*—Grasp the blossom with the thumb and fore finger of one hand, and grasp the tips of the petals with the thumb and fore finger of the other hand (Plate I.), then, by simply giving the wrist a quick upward or downward movement, the petals can be easily detached from the blossom (Plate II.). Now, with one or two quick movements with the scissors (Plate III.) the anthers are removed and the pistils are ready to receive the pollen (Plate IV.). After the application of pollen is made, the

PLATE V.—METHOD OF BAGGING THE BLOSSOM

emasculated blossom is enclosed within a bag (Plate V.) and allowed to remain until fecundation has taken place and all danger from the action of foreign pollen is over. After every pollination, label each bag in such a way that there will be no question as to what variety of pollen is used. As the apples approach maturity it is essential that they be enclosed in cheese-cloth bags. This protects the fruits from being picked accidentally. The object in removing the petals is to tell just where to make the cuts without injuring the other parts of the flower. Since this greatly facilitates the method of emasculating, it may serve as an impetus for greater work along this line.

Several methods of emasculating the blossoms are used by different investigators throughout the United States. Waite, of the

PLATE VI.—FIG. 1. IMPROPER EMASCULATION, SEPALS BEING INJURED. FIG. 2. PROPER EMASCULATION, SEPALS INTACT

Department of Agriculture, removes the corolla with the aid of a small sharp pair of scissors, leaving the emasculated blossom as seen in Plate VI., Fig. 1. Others have been fairly successful in using a sharp scalpel to perform the work. We have found that in every case when the sepals were removed with the petals it caused a malformation of the apple, as shown in Plate VII., Fig. 1. Fig. 2 shows a normal apple when sepals are unmolested.

It is evident that emasculating must be skillfully done, for the slightest mutilation causes a malformation of the calyx end of the apple. When the sepals were not injured in any way a large per cent of the emasculated blossoms set fruit. Plate VI., Fig. 1, shows the wrong way of emasculating, and Fig. 2 the correct way of emasculating. The method of removing the blossoms as outlined by the writers leaves the blossoms in perfect condition, with the fruit unharmed.

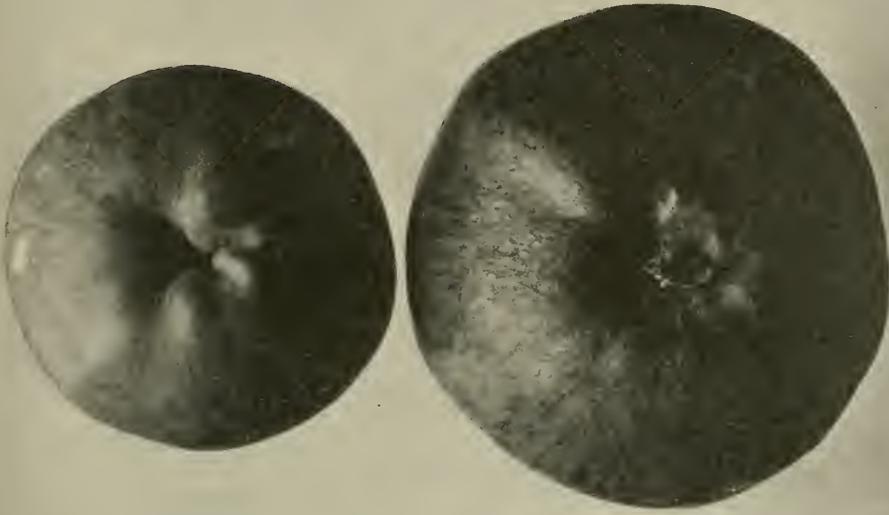

PLATE VII.—FIG. 1. MALFORMATION, CAUSED BY CUTTING SEPALS WHEN EMASCULATING.  
FIG. 2. NORMAL APPLE, AS A RESULT OF ALLOWING SEPALS TO REMAIN.

#### COLLECTING POLLEN.

One of the greatest problems the plant-breeder has to meet is the collecting of an adequate supply of pollen for work on a large scale. It is evident that, where many of our leading varieties blossom together, pollen must be gathered in sufficient quantities beforehand, if extensive experiments in cross-pollination are to be carried on.

Since this is the case, means must be provided by which the blossoms can be forced. To accomplish this, a forcing-house is very desirable, although for work on a small scale any house having quite a few windows on the south side would answer the purpose.

*Selecting Twigs.*—Small twigs, from ten to twenty inches in length, having from three to six clusters of blossoms, are gathered from the variety which is to be used as a pollinizer, and taken to the forcing-house. First, all the open blossoms are removed from the twigs, which are then placed in jars of water and properly labeled, then covered with hoods so as to prevent the transfer of pollen by insects.

Usually the twigs are placed in the forcing-house a week or two before the trees come into blossom. If the weather is good the blossoms will open in three or four days. If, however, it is desired to obtain quicker results, it can very easily be accomplished by using warm water in place of cold. By split-

ting the stems of the different twigs the blossoms can be forced open from three to four hours earlier. In the experiments carried on, a gain of from one to two days was realized by the use of warm water and the splitting of stems.

After the anthers dehisce and the pollen becomes ripe, a small vial properly labeled, is used to collect the pollen. By removing the hoods the pollen can be very easily dusted into the vials with the aid of small camel's-hair brushes. Plate IX shows the vial, properly labeled and plugged with cotton, which is used by the writers to carry the pollen to the orchard. In these vials the pollen will keep until ready for use, if sufficiently dried. If it is not dried enough, fermentation will set in quite easily. Very gratifying results have been obtained by collecting the pollen in this manner. At the present time it is not known just how long pollen can be kept before losing its viability. At this station good results have been received from pollen that had been gathered three weeks.

One of the simplest ways of procuring pollen is to cover with paper sacks branches that are nearly in flower, and the ripened anthers from these blossoms can be used for pollination purposes. Another method is to put in a warm room unripe anthers from flowers about to open. In a few hours the

anthers will dehisce. Many pollenizers use this method in cases of emergency. Perhaps the most popular way of collecting pollen is to pick off the unopened buds, remove the anthers, and let them dehisce.

After trying some of these methods outlined we decided that better results could be obtained by the use of the forcing-house. In a house twelve by fourteen feet, containing from twelve to thirty jars of blossoms, sufficient pollen can be gathered to carry on very extensive experiments in cross-pollination.

#### APPLYING POLLEN TO THE PISTILS

We have found that the quickest and most effective way of applying pollen to the pistils is by the use of a small pointed camel's-hair brush, having a handle from six to eight inches long. (Plate IV.) While in this way more or less pollen is wasted in making the application, nevertheless the disadvantages are greatly offset by the advantages. Brush pollination is very effective, also allowing for great ra-

PLATE XIII.—BLOSSOMS READY FOR EMASCULATION.

This should always be done before the petals unfold. However, when possible emasculation should be delayed until the petals are nearly ready to open.

PLATE IX.—SHOWING METHOD OF COLLECTING AND TRANSFERRING POLLEN

pidity; and when a great many thousand blossoms must be pollinated it is the most practicable method used. The simplest way of applying pollen is to touch the stigma with a dehisced anther. Another method is to dip the thumb or fore finger in the pollen and then transfer to the stigma of the pistil.

When using the camel's-hair brush too much care can not be exercised in making the application. Enough pollen should be placed on the stigma so that it can be readily perceived. In all cases each kind of pollen for each variety pollinated must have its own brush if scientific results are to be obtained. By sterilizing the brushes they can be used over and over again.

#### WHEN TO MAKE APPLICATION.

There appears to be considerable controversy as to the best time of applying the pollen to the pistils. The indications are that much depends upon the maturity of the buds whether or not a pistil is receptive at the time of emasculating. The receptiveness of the pistil is also influenced by such elements as climatic conditions, vigor and age of tree, variety, condition of soil, and general care of orchard.

The paramount question to settle is whether better results can be obtained by applying the pollen at the time of emasculation or waiting until the pistil is receptive. From the deductions made of the work carried on by this station, excellent results have been obtained by applying the pollen to the pistil

as soon as the blossom is emasculated. However, this may have been due to the fact that the blossoms operated upon were those that would probably open under normal conditions in one day from the time the operation was performed.

From the results obtained it is evident that in a great many varieties the pistils are receptive before the blossoms open. This being the case, it tends to show that nature encourages cross-pollination rather than self-pollination. One of the greatest advantages of pollenizing at the time of emasculating is the saving of time, as the bags will not have to be removed.

There are many plant-breeders that do not make the application until two or three days after the blossoms have opened. These men have also received very satisfactory results. Professor S. W. Fletcher, of the Virginia Agricultural College, usually waits until the stigma of the emasculated blossom glistens before making the application. Many other investigators pursue the same method. By consulting Tables IV. and VII. the percentages of successes of the two methods can be readily seen.

#### POLLEN TRANSMITTED THROUGH THE AIR.

It has been a question in the minds of many experimenters for some time just how much the wind aids in carrying pollen from tree to tree. If the wind does aid in distributing pollen, is it distributed in sufficient quantities to insure the fertilization of the ovules? Since so many of our varieties of apples are known to be self-sterile, and must depend upon

foreign pollen for fertilizing the ovules, this question is of serious consequence. Is it the wind or our common honey-bee that does the work? From the observations made the past two years it is evident that bees play an important part in the fertilization of the blossoms. To arrive at some definite conclusions as to how much pollen is transmitted through the air by the wind, experiments were carried on to determine this question. Waugh, of Massachusetts, demonstrated that plum pollen was not transmitted through the air in sufficient

PLATE XI.—EMASCULATING AND BAGGING BLOSSOMS.

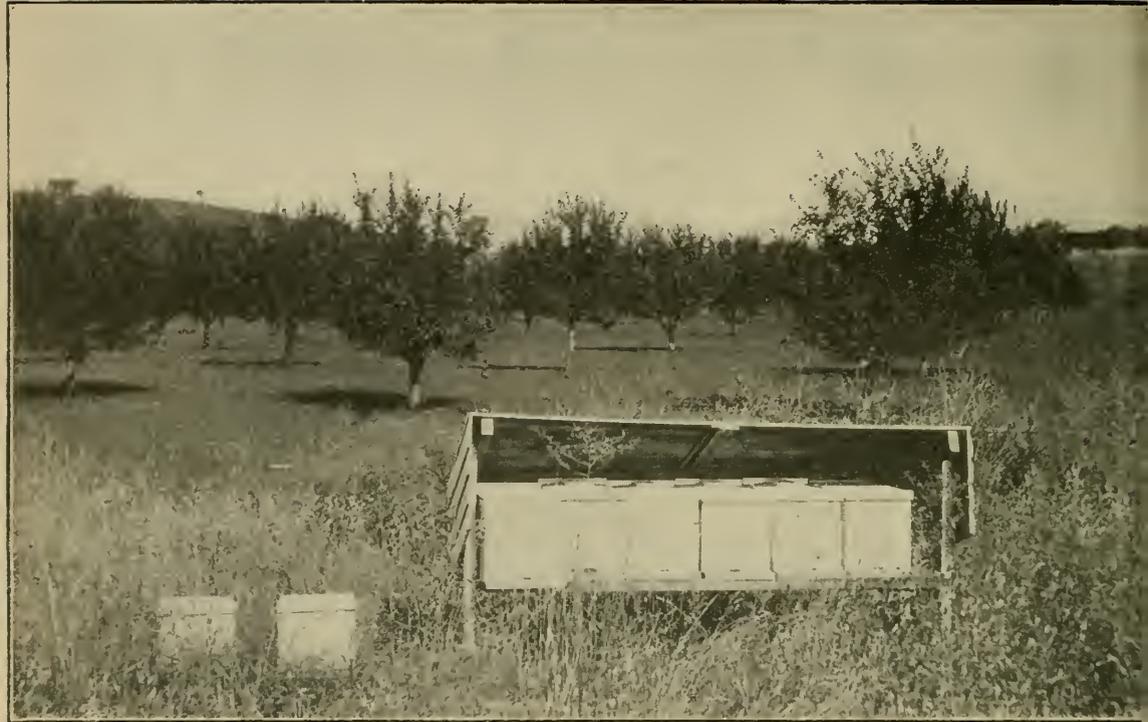

PLATE X.—APIARIES SHOULD BE KEPT IN ORCHARDS, AS THE BEE IS THE BEST AGENT FOR CROSS-POLLINATION.

quantities to insure cross-pollination. To substantiate his statements the authors carried on some experiments with plums, as outlined by him.

To determine whether apple pollen was carried through the air by the wind in sufficient quantities to insure cross-pollination, experiments were conducted in the following manner. Small glass slides, one by three inches, were smeared with vaseline and placed at different distances and at different heights from certain large trees in the orchard. In this case, two of the largest trees in the orchard, the Rome Beauty and the Mammoth Black Twig, were selected. After an exposure of twenty-four hours the slides were taken to the laboratory and examined under the microscope. The following indicates results obtained:

TABLE I.—SHOWING DISTRIBUTION OF POLLEN BY WIND.

Slide number.	Distance from trunk of tree.	Height of slides.	Number of pollen grains.
1 .....	4 feet	On ground	16
2 .....	12 feet	6 feet	9
3 .....	15 feet	4 feet	11
4 .....	15 feet	6 feet	8
5 .....	20 feet	9 feet	6
6 .....	30 feet	6 feet	7

During the experiment a strong north wind was blowing, and the trees were in

the height of their blooming period. The conclusion to be drawn from this experiment is that the wind can not be relied upon as an agency to transfer pollen from tree to tree throughout the orchard.

To verify our last experiment the following work was carried on: A seven-year old tree containing 1500 blossoms was emasculated and left exposed to the wind and insect visitation. The object of this experiment was two-fold: First, to determine if pollen was transmitted through the air in sufficient quantities to insure cross-pollination; second, to determine if removal of the floral part of the blossom would affect the visits of insects. The tree operated upon was located twenty feet from another tree that blossomed profusely. It is generally conceded by many experimenters that the honey-bee is attracted to the blossom by the inflorescence. The results obtained will be a fair index as to the truth of this statement. Out of the fifteen hundred blossoms emasculated, only five set fruit. During the whole period that the pistils of these blossoms remained receptive, only eight bees visited the tree. More than twice that number were seen in one half hour on the tree twenty feet away. Since only a small portion of the emasculated blossoms set fruit, it is manifest that pollen is not transmitted through the air in sufficient quantities to in-

sure cross-pollination. While this experiment demonstrated the fact that bees will visit trees when the floral part of the blossom is removed, they are not attracted in sufficient numbers to insure perfect pollination. It is apparent that the showy petals of the blossoms aid materially in attracting the bees. The blossom is well supplied with nectar, and the open character of the nectary makes it accessible to almost all insects. The bees, in trying to reach the nectar, brush against the anthers and carry away with them on their hairy legs and abdomen large quantities of pollen. The insects in visiting other blossoms transfer some of the foreign pollen to these pistils. Since the wind aids so little in cross-pollination it is evident that the various insects, especially the bees, are carriers of pollen.

As the assurance of a crop depends upon insects as distributors of the pollen, it is necessary that apiaries be established in the different fruit sections. With favorable climatic conditions and proper planting of varieties the bees would insure pollination.

#### SELF-STERILE AND SELF-FERTILE VARIETIES.

A knowledge of the sterile and fertile varieties is essential in pollination work before any definite investigations can be conducted. A sterile variety is one that will not fertilize its ovule with its own pollen, while a fertile variety is one that will perform this function. Since investigators have found that climatic conditions influence greatly the sterility and fertility of a variety, it is doubly important that this experiment be demonstrated in every locality, especially when a wide variance is found in the climate. Eastern conditions are hardly applicable to those found in the West.

The method usually followed to ascertain this question was to inclose the blossoms in cloth or manilla bags before they opened, thus removing all danger of foreign pollen from insect visitation. After blossoms open and the anthers expand, the pollen is scattered on the several stigmas; and if the blossoms set fruit it is evident that the variety is self fertile; but, on the other hand, if the pistil shrivels and dries up it is sufficient evidence that the variety is self-sterile. For this experiment it is very important that the right branches be selected. Outside branches should be chosen, as they are more favorably situated. In every case all the open blossoms should be removed before sacking. Too much stress can not be placed upon this important question if accurate results are to be realized.

In 1907 three grades of bags were used, namely, the manilla paper bag, the fine and the coarse cheese-cloth bags. Since inclosing blossoms in bags is subjecting them to unnatural conditions, these three styles were selected in order to detect, if possible, any difference that might arise in the setting of fruits. As the effectiveness of the three bags was the same, in 1908 we confined ourselves to the manilla bags.—*Better Fruit.*

## BEE-KEEPING IN HAWAII.

BY ALBERT F. JUDD,

*President of the Hawaiian Bee-keepers' Association.*

Bee-keeping in Hawaii can not be understood without appreciating some geographical facts. Hawaii is north of the equator. It is a full-fledged organized territory of the United States, and consists of eight inhabited islands. It is just as much a part of the United States, so far as the laws go, as the Territory of New Mexico or Arizona. It is a white man's country, although the majority of residents are Chinese and Japanese. In area the islands equal approximately the area of Connecticut. We have two mountains on the large island of Hawaii (from which the group takes its name) each of which is very nearly 14,000 feet high. We have all degrees of climate except the intensely hot climate of the pure tropics. A glance at the map will show that the islands are close to the Tropic of Cancer. The cool ocean currents from the Pacific Coast, with the northeast trade winds, make the climate never oppressive, even at sea-level.

The first honey-bees were introduced into the islands in 1857. In the '90's, bee-keeping began as an industry. Its beginning was slow, and it was not until January, 1907, that the bee-keepers came together and formed the Hawaiian Bee-keepers' Association. Our present membership is thirty-seven, and includes all those engaged in the production of honey and wax for profit, besides others interested in the industry scientifically or for pleasure.

The honey and wax industry in this Territory is valued at approximately \$200,000. About \$30,000 worth of honey was produced during 1907, and \$6000 worth of wax. We estimate the number of colonies at present in the Territory at 20,000, and it is believed that this number can be doubled. If this is done, the normal honey flow is expected to produce about \$100,000 worth of honey and wax. The bee-keepers of Hawaii spend annually between \$2000 and \$3000 for supplies, most, if not all, of which come from the mainland of the United States.

There is at present in our association a spirit of cooperation, not only among the members—resulting in an interchange of ideas on the many problems existing in the apiaries and in the marketing of the product—but also between the association and the various officials of the Department of Agriculture at Washington and the local agricultural station under whose jurisdiction matters pertaining to the industry more directly come.

At the present time the diseases of American or European foul brood are not found in the Territory. We have secured protection from the introduction of these diseases by legislation.

Another work that our association has taken up is the introduction of plants and trees to improve the bee pasturage, and satisfactory progress has been made. The food

and drugact of June 30, 1906, passed by Congress, has brought Hawaiian honeys into prominence because of the chemical composition of some of the honeys elaborated by our bees from honey-dew, and we assisted in adjusting these matters by sending Mr. D. L. Van Dine, Entomologist of the Hawaii Experiment Station, to Washington. Our association also has had as its guest, recently, Dr. E. F. Phillips, in charge of the office of apiculture at Washington, who has made an examination of bee-keeping in Hawaii, and whose report thereon is awaited by us with interest.

We appreciate the opportunity afforded by GLEANINGS to get in touch with the industry on the mainland. We are open to suggestions for improvement. Any thing that can improve the honey-bee and its products is eagerly sought for by us.

---

### NOTES ON TRANSFERRING.

#### Tools and Appliances for the Same; the Direct vs. the Indirect Method of Transferring.

BY F. DUNDAS TODD.

In the past two years I have been concerned with the transferring of over three dozen frame hives and one box hive to the style that I favor, so that I have had a chance to improve a little on the procedure that I described in an article two years ago. I have worked both the direct and the indirect systems; but after taking into consideration all the factors, methods, and results I can not make up my mind which is better.

Direct transferring is an occupation I would not of choice care to follow up day after day for a few months; but, on the other hand, it has ceased to have any terrors for me, as, with suitable arrangements and the aid of an assistant, I have handled three hives per hour for several hours in succession.

In direct transferring one gets through with the job at once; the hive is speedily at work in a normal condition, and, best of all, the proposition is off one's mind. My experience with indirect transferring (or what is known as the Heddon method\*) was in a poor season, and so I saw it at its worst; but it took over three months to get rid of the last of the odd-sized frames, and all the time I felt I was hindering the work of the bees.

In transferring direct I feel I have made some new departures that are advantageous. The slop of honey annoyed me greatly, but I hit upon the idea of doing all the cutting of the combs and all the fitting of them into the frames in a tray whose dimensions are 12×20×2 inches; in fact, one of my feeder trays, whenever it got sloppy it was a simple matter to turn the hose pipe on it when such was handy, or to rinse it out with a pailful of water. In actual practice I found it neces-

sary to wash the tray after a hive was treated, and no oftener. On my left hand I had a similar tray for reserve bits of comb; on the right was a pail into which the scraps were dropped, these being made up principally of drone comb.

In transferring my own hives I had the use of a barn with a screen door so I could carry in two frames at a time, and work without being bothered by the bees. Of course, I wore a veil; but my fingers were uncovered from the knuckles down, and I can not recall having received a sting. When helping a friend with nine hives I worked in a barn without a screen door. He carried the combs; I did the cutting and fitting; but it was not until we got to the last hive that I began to get my fingers stung. By that time a steady stream of bees was working all around, so I had to select the spots before I touched a comb. Occasionally I guessed; and whenever I guessed wrong—well, I quickly found out the difference between bee and no bee. When the job was finished, there was not a bit of slop on the bench or floor to indicate that about 80 combs had been cut to pieces; and this, too, in August, when combs were heavy with winter stores.

Using the shallow extracting-frame I have rarely any call for string. Wire nails about two inches long are good enough. When the comb neatly fits the frame, all that is necessary is to insert nails in each of the four wire holes at the ends of the frames; then with an awl bore a hole through the middle of the top-bar; push in another nail, and the frame is ready for the hive. To get an exact fit, I find the best thing to do is to have a piece of board the exact size of the inner dimensions of the frame, and use that as a guide, for one gets perfectly square cuts; but if we use the frame itself, the cut is generally on the angle—at least that is my experience.

With pieces of comb smaller than the frame area I find it best to work to square-cornered shapes, trying always to get pieces reaching from top to bottom of the frame. Extra nails in the top and bottom bars within an inch of the joining of the pieces of comb generally keep all in shape. There is much virtue in a tight fit, so I never hesitate to squeeze a scrap of comb into a solid mass and force it between the side of the frame and the comb. The bees remove these in due time.

In the season of 1909 I tried indirect transferring with over a dozen hives—some of them Gallups, with frames about a foot square; some almost Langstroths; others, Jumbos. The spring had been backward, so it was not until the end of May that I could start the campaign. As opportunity offered, I transferred the empty combs and placed them in a two-story divisible hive; then the old frames were added. The Gallup frames, being short, had to be provided with extra top-bars, which were screwed to the old ones. While some other frames that were too long had to be shortened. Any way, bit by bit I got all the frames into divisible hives, always

\*For a description of this method see the A B C and X Y Z of Bee Culture, under the head of "Transferring."

working the old frames to the sides as the hives grew stronger; then when they were clear of brood they were removed and transferred. The season being a blank one, new combs were built slowly, and I had no spare ones, so it took until the end of August, over three months, to get rid of the last frames. In an average season I fancy six weeks would be enough.

Whatever may be the usual conditions I don't know; but this season I noted particularly the bees speedily united pieces of comb whose line of contact was perpendicular; but they merely gnawed the edges above and below when the junction was horizontal. None of such combs were put into use, so I have them stored away, and will try them again next season, when the honey-flow is on, and see what the bees will do about them.

Victoria, B. C.

### NO CARBOLIC ACID USED IN SPRAYING FRUIT-TREES.

BY R. F. HOLTERMANN.

That carbolic acid will prevent the visits of bees I am quite sure, for I have used it frequently to drive the bees out of comb-honey supers—a plan I learned from European bee-keepers. A weak solution, one that will not burn the skin, is prepared, a cloth dipped in it, and wrung out. This cloth is then laid on top of the supers, and the bees will leave the sections with a rush. No doubt this same odor would also keep the bees away from the blossoms.

But here in Canada the fruit-growers find that they are jeopardizing their crop if they spray the trees while in bloom. Just think of covering the sensitive and delicate portions of the blossom with a spraying solution! The pollen would very likely be injured and kept from being distributed, and the portion of the blossom to receive the pollen would in many instances not be in the right condition. The addition of carbolic acid would not overcome this difficulty for the fruit-grower. So far as I know, there is less and less of this practice of spraying trees in bloom in our country. In an orchard where some varieties or kinds of fruit bloom sooner than others, there is a strong temptation to spray all at one time, so some are apt to be sprayed while in bloom; but I have been told of very bad effects to the crop of fruit after such work, and I fancy that this fact is now pretty well known.

In regard to the use of carbolic acid, I wrote to Mr. P. W. Hodgetts, Department of Agriculture for Ontario, who is secretary of the Ontario Fruit-growers' Association as well as of the Ontario Bee-keepers' Association. I received the following reply:

*Dear Mr. Holtermann.*—Yours of the 18th is at hand. So far as I know I have never heard of any of our fruit-growers using carbolic acid for the purpose of preventing bees from visiting fruit-blossoms. Carbolic acid is not used in any of the formulae that we send out from this office for the spraying of fruit-trees at blossom time. It is used in a limited way in connection with some of the washes for scale insects in cer-

tain sections of the Western States, but very little in this country. It is also used to replace the Bordeaux mixture in grape-spraying by a few men in the Niagara district, but is not recommended by this Department.

P. W. HODGETTS.

Toronto, Jan. 21, 1910.

### BEE-KEEPING NOTES FROM TEXAS.

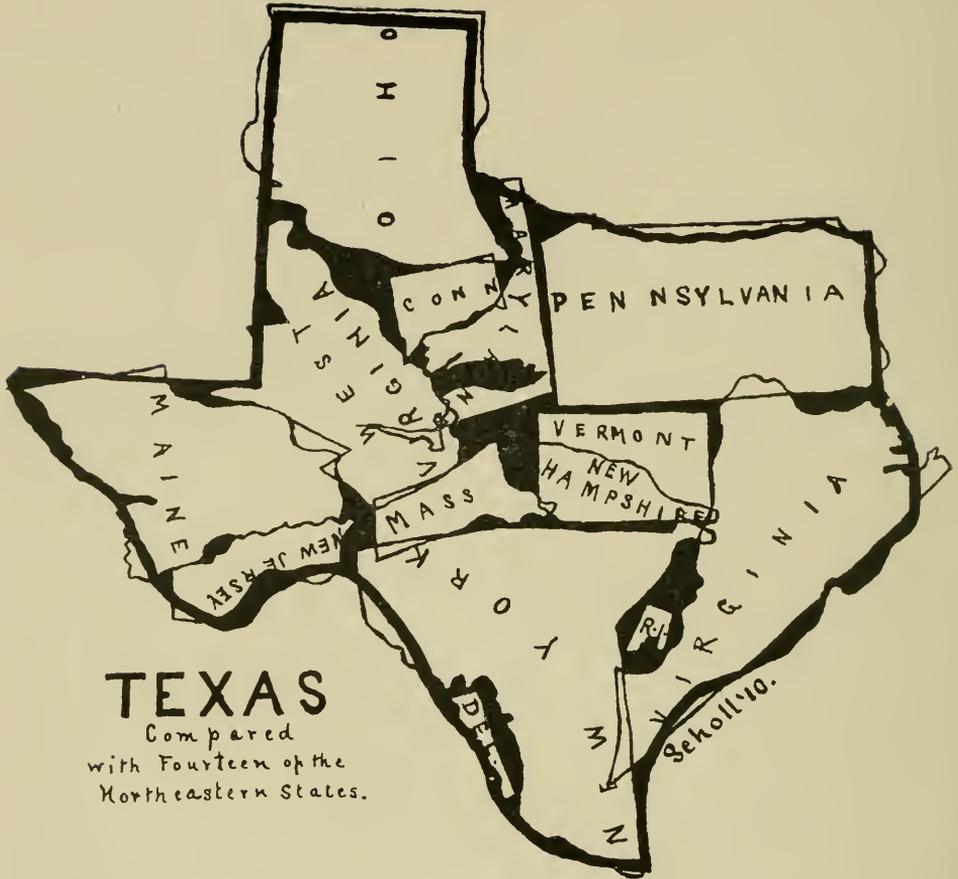

#### The Widely Differing Conditions of Climate, etc. in the Lone-star State.

BY LOUIS H. SCHOLL.

With the splendid prospects for one more of those good old-time honey crops in our charming southern country there has been a marked revival of interest in bee-keeping and a renewed activity among the bee-keepers. And not only have our own bee-keepers been influenced, but it seems from the numerous inquiries from outsiders concerning Texas that this influence has spread to all parts of the country, attracting more interest to bee-keeping in the great Lone Star State than in any other country at the present time. We are proud of this, for no other country (we call Texas a "country," for she is too big for a State) has made such great strides. While Texas is *the* leading State in the Union as a honey-producer, yet bee-keeping here has not nearly reached that stage of development that exists in most of the other States. The annual output of honey is enormous, but we know that there are thousands of acres wasting millions of pounds of nectar that could be saved by the up to date progressive bee-keeper.

It is impossible to give any idea in figures of the honey produced in this State in average years, as it has been impossible to obtain any thing like reliable statistics. This is due to the fact that almost the entire product is consumed at home, a very small part of it going outside of the State, and then only into adjoining ones. In that sense Texas is a State of its own in the production of honey, consuming what she produces herself. It is to be hoped that the new census will aid us in ascertaining approximately, at least, what our annual product has been the past year. From this it would then be possible to draw an idea, but an idea only, as, since the honey crop was a short one the past year, the showing that will be made in the census figures will by no means give us the output of an average year. But the fact remains that Texas is the leading State for output of honey, number of colonies of bees, and as a honey-producing State as regards the vastness of its area, its great variety of locations, soils, and climatic conditions.

On this account I wish to call the reader's attention to a few facts. After trying to cover up Texas with fourteen other States, as shown in the engraving herewith, it was found that it was still quite in evidence, as shown by the black parts of the picture. Now, this shows the vastness of its territory as compared with that of Maine, New Hampshire, Vermont, Massachusetts, Rhode Island,

Connecticut, Maryland, Delaware, New Jersey, New York, Pennsylvania, Virginia, West Virginia, and Ohio—the whole of northeastern United States. Imagine the great number of localities there must be in this vast stretch of country, from north to south and east to west! Then the variety of bee-keeping conditions, both in latitude and altitude, must be taken into consideration. While we have conditions not far different from those of some of the States of the North, we also have conditions of the very tropics. These will be described a little more fully in a succeeding article.

But there is a reason why this comparative map is shown. Letters by the score have come to me, something on this order: "I would deem it a great favor if you would take just enough time to tell me in a few words where I can find a good location, on a railroad, near school and church, and close to some city, with good roads to market my crop. I expect to pull up stakes here, but would like to have you tell me where to go before making the move to a new place." One of the main things left out in the letter above is that the writer has not mentioned the kind of church he belonged to so I might

have looked after that; also, in selecting the suitable spot.

Now look at the map before us and let us ask ourselves this question: Am I thoroughly familiar with bee-keeping matters and the bee-keeping locations of the fourteen States, from Maine, Indiana, and down to the Carolinas? Could I tell a man "from Texas" just where he might locate in a little "nest" as is requested in the sample of letter above? I must admit that I could not. Now consider the vast difference in climatic and other conditions, more especially the flora of that State, which exist in Texas—much more varied than throughout the fourteen States here shown, stretched over a much greater area, and then ask whether it is really right to write for such information to one single little "six-foot-three" fellow, who is only an invisible speck on the face of the great Long Horn State.

Considering all the above, the best way for a prospective Texas bee-keeper to pursue is to take advantage of one of the many cheap home-seekers' excursions run every summer, to come to Texas, spend some time here, look over the ground thoroughly, select a place, and then, and not until then,

pull up stakes where previously located. Then when once here, as a bee-keeper of this great State, the new comer should make up his mind that he is going to like the new place and the *new State*. We want no people here who are always dissatisfied, no matter where they are nor what their lot is. There are such that are always grumbling about their surroundings. We do not need them. But the real, energetic, interested hustler has a chance, if he will try things and stick to it. It must be remembered that we have adverse seasons here sometimes as well as elsewhere; however, these have been comparatively few, and, taking year for year, our seasons have been above the average as compared to other parts of the country. Taking it all in all, Texas bee-keeping has a brilliant future. All we have to do is to stick to our business, improve as we go along, and our efforts will not be in vain.

New Braunfels, Texas.

### COMB VS. EXTRACTED HONEY.

**Comparative Results of Comb and Extracted Honey Production in the Buckwheat Regions of Eastern New York; Buckwheat as a Honey-plant.**

BY FRED G. MASON.

My father began bee keeping in 1864, and continued in the business to the time of his death, in 1898, leaving me at that time with 84 colonies in winter quarters. I was brought up in the business, and often helped him when not otherwise employed. I read the bee-journals from early boyhood. Hearing of E. W. Alexander and his large apiary in New York I became very much interested, and finally managed to spend ten days helping him during the busy season. This was a most profitable and pleasant experience, and I will long remember Mr. Alexander's kindness to me in answering questions and giving me the benefit of his experience and advice.

It was due in a great measure to Mr. Frank Alexander that I was placed in sole charge of a good-sized apiary in the buckwheat country last season. The 226 colonies in this yard had gone into winter quarters in the fall of 1908 in very good condition by reason of a continuous light flow from buckwheat, which kept the bees rearing brood long past the usual time (a condition that was quite reversed last fall). The bees were taken out of the cellar April 2 and 3, 1909, and had a fair flight. By the middle of May the apiary consisted of about 210 colonies which had survived the severest spring weather that I can recall. As soon as fruit-bloom came, weather permitting, I began overhauling the bees, equalizing stores, clipping queens, etc. I soon noticed that most of the honey in the hives was candied as hard as a board, the bees using it of necessity rather than of choice. I reasoned that, as soon as they could obtain new honey in a sufficient

amount to keep up brood-rearing, they would no longer touch this old honey, and it would be in the way, in many cases, enough to curtail brood-rearing sadly. Therefore, as soon as the bees were bringing in new honey sufficiently I began removing this candied honey, substituting the best breeding-combs that I could select from the stock of extracting-combs, always leaving a frame or two of the candied honey for outside frames. I usually selected the lighter combs to remove, for fear that weather conditions might prevent a continued supply of new honey.

On my second trip over the yard I found quite a number of colonies that had almost reached their limit in brood-rearing, and to such colonies I gave a second story containing the best of the empty brood-combs with a comb of candied honey, from which the cappings were removed, next to each side wall. Soon there were great slabs of brood in those second stories, and the bees were bringing in clover honey quite freely. I soon reduced the colonies to one story each, helping out the weaker ones with sealed brood from the stronger ones, and forming new colonies with extra combs of brood not required for this purpose. These new colonies were, for the most part, supplied with laying queens. This apiary was equipped for both comb and extracted honey, and I was obliged to run for both, even though I already had a preference. The prospects for next season were good, sweet clover being quite abundant, and many fields of alsike giving promise of full bloom. Basswood, moreover, was plentiful and the trees were a sight to behold, being weighted down with buds the like of which I had never seen before.

In placing comb and extracting-supers on the hives I was very careful to pick out the most powerful colonies for the comb-honey supers, leaving the rest for the extracting-supers, and after finishing this work I found that the comb-honey colonies outnumbered the others. I had plenty of bait-sections, so I usually used ten in each super, five of them being sections that had perhaps been worked on a little, the other five being quite well drawn out.

The white honey-flow did not prove to be as great as I expected, for, with the exception of a few days, the weather was anything but ideal. The nights were very cold, and the days were nearly always cool and often windy. Along in April the bees did not usually go to the fields until the morning was well advanced, and by three o'clock work was almost at a standstill because of the cold. Notwithstanding these adverse conditions I secured what many would call a fair crop of white honey, and removed both the comb and extracted honey before the bees made much headway on buckwheat. At least 90 per cent of the extracted honey was sealed when removed. I soon had empty supers in place ready for the buckwheat crop.

I was very much surprised when I came to compare the results of the comb and ex-

tracted-honey colonies after this light flow I found that the extracted colonies eclipsed the others in the amount of surplus honey secured, and that, too, at fearful odds as to strength and working force. To be sure, I had made some changes with a few comb-honey colonies on account of their swarming, running them for extracted honey for a short time. In some cases I did not change them back; but still these changes did not greatly affect the result, as they were usually offset in some way.

I decided to take particular pains during the buckwheat flow to determine, if possible, the comparative merits of producing comb and extracted honey. I again used the most powerful colonies for comb honey, selecting 120 colonies for this purpose, leaving the remaining 100 for extracted honey. The first buckwheat in bloom was a large field of Japanese. The weather was quite satisfactory, and the bees were doing well. Other fields began to grow white; but the weather became less and less favorable until the buckwheat reached its prime, while the bees were shut in entirely for about twelve days on account of the cold and wind. There was a large acreage sown to buckwheat, and quite a portion of it was late, so I hoped that the bees might yet have a fair show. It lasted very late, and the weather warmed up a little; but the buckwheat did not yield much, in spite of the fact that there had been no frosts. I began removing both comb and extracted honey, using bee-escapes. It took two days or more for the bees to get down out of the supers, yet this was by far the most satisfactory way.

The extracted colonies yielded all of 5400 lbs. of nice honey, the greater part of it being sealed when removed, and there was plenty left for winter stores, with the exception, perhaps, of two or three. The comb-honey colonies produced less than 2500 lbs., much of which was not well finished, and these colonies also were left heavy in stores for winter. The total crop for the season amounted to something over seven tons. If the yard had been run for extracted honey wholly, there would have been much better returns, together with a smaller cost of labor.

#### AMOUNT OF BUCKWHEAT NEAR DELANSON.

When I was helping Mr. Alexander I asked him what he thought the acreage of buckwheat was within his bee-range; and after a moment he said it was probably all of 1500 acres. I did not question his assertion in the least; but it was my privilege last fall to prove to my satisfaction that Mr. Alexander's estimate was most conservative. I remember reading of Mr. Orton's visit to Mr. Alexander in the fall of 1908, as mentioned in his article in GLEANINGS, in which he stated that he was a farmer and could judge the size of fields fairly accurately, and that from Schenectady to Delanson, a distance of fifteen miles, he had estimated the number of acres as being not more than forty-five. Now, if Mr. Orton had made a complete circuit of the Alexander yard, for 1½ miles in every direction, he would have found single fields that contain-

ed more than forty-five acres. I interviewed a local thrasher, this fall, when his season was over, and he told me that he had thrashed over 13,000 bushels within 1½ miles of the yard which I had in charge, and he said he was sure that he had not thrashed half of that which was grown in this space. I asked him what the average yield was per acre, and he said 25 bushels. This would make more than a thousand acres of buckwheat grown within 1½ miles of the apiary. If a radius of two miles were taken there would be more than double this amount—that is, more than 2000 acres of buckwheat that the bees would have access to in fair weather. One season the former owner of the apiary sowed quite a field of buckwheat earlier than any sown by his neighbors. The season happened to be such that he obtained practically all of his buckwheat honey that year from this one field. I mention this to show that an extra large acreage of buckwheat often cuts but little figure in the crop of honey. Had the area sown to buckwheat in this section last season been so increased as to make one continuous field to the limit of the bees' flight, I very much doubt whether it would have added much if any to the amount of honey secured. My belief is that a section of country that has, say, 500 acres of buckwheat in bloom within easy range of an apiary, will produce all the nectar that a large apiary can bring in. Much more than this amount would not help the bees during the time they were gathering their loads of nectar, whether the blossoms were yielding bountifully or meagerly.

### MOVING BEES UNDER IDEAL CONDITIONS.

BY G. C. GREINER.

The various experiences of a lifetime had forced me to believe that moving bees, even under the most favorable conditions, was an unpleasant job. But my last venture of this kind has convinced me that it can be done, not only comfortably but with a considerable degree of enjoyment as a winter sport.

Last May I moved about half a mile from the old home, and the question arose as to how and when it would be best to move the bees. They could have been moved at the same time; but their former location being so near by, and the season far enough advanced so that all field workers had generally formed their lines, many would undoubtedly have gone back to their former stands and perished.

I decided to leave my bees at the old place during the summer, and work them somewhat like an outyard, intending to move them, during the winter, on snow. This would be an easy matter if the hives could be loaded singly, with perhaps the help of a boy, on to some kind of sleigh rig when we had sleighing. But the bees had to be packed for winter when they were in proper condition before the snow came; and after they

G. C. GREINER'S METHOD OF MOVING COLONY SLEDS IN WINTER.

were packed they were in sheds holding five colonies each, and weighing about 500 lbs. To load one of these sheds and handle it as carefully as bees should be handled would require a number of hands, which would be difficult to find just when I wanted them.

At first the undertaking looked a little dis-

being raised. The tool at the left is the lifter: the drawing makes it plain enough so that a description is not necessary. With the roller attachment, which I consider a great advantage, it works so smoothly that it does not jar the sheds in the least when being operated.

In their natural positions all sheds are blocked up about six inches from the ground; and to load them, each one had to be raised from four to six inches from their foundation. To do this the left end of the shed is raised first, just high enough to let the little bench take its place. Then the other end is raised about

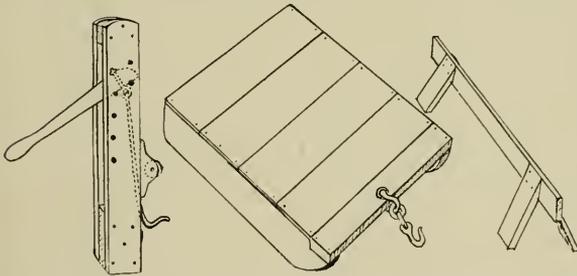

FIG. 1.—TOOLS FOR LOADING AND MOVING SHEDS OF BEES.

couraging, but after manufacturing the necessary tools and contrivances I succeeded so well that I did the whole business easily without the help of a single person.

The tools I used in loading and moving are shown at Fig. 1. In the center is the rig I used for moving. It is a combination of sleigh and stoneboat. The runners are 3×6-in. timbers, with a level one-inch platform on top. At the right is a bench about 12 in. high, made like a common saw-horse. It is used to support the shed after

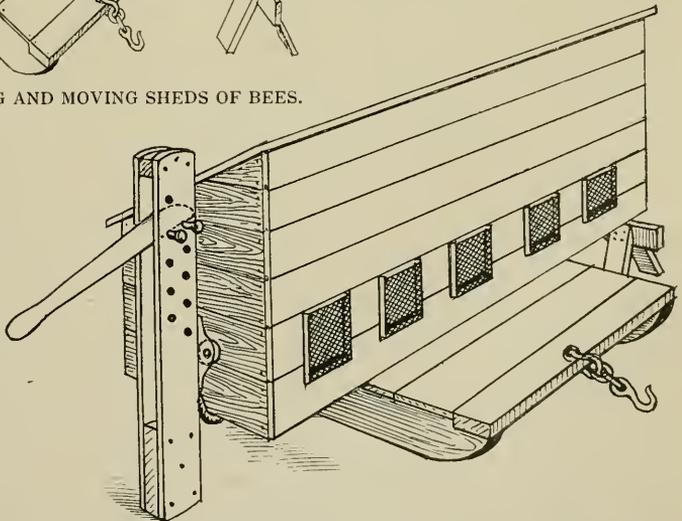

FIG. 2.—ELEVATED SHED WITH SLED IN PLACE READY FOR MOVING.

the same distance from the ground, and the sled put in its proper place. Fig. 2 shows the shed in that position with the sled in its place ready for loading.

When unloading, the shed is first raised from the sled in the same way as when being loaded; and after the sled is removed, the shed is lowered on to its foundation-blocks again.

By the use of the tools here described I was able to handle all sheds in such a steady, quiet way that the bees hardly noticed the operation. The conditions of the weather were also very favorable for the job. We had from 8 to 10 inches of fresh snow; and as I selected thawy days for the moving, when the old snow below was soft, the trips were made without a jar, jolt, or jump to disturb the bees. In only a very few instances could small clusters be seen inside of the screens, and most of them went back before their sheds were unloaded.

## RESULTS OF BEE-KEEPING LEARNED FROM BOOKS.

### A History of a Beginner's Mistakes and Experiences.

BY MARTHA K. PURSELL.

*Continued from last issue.*

#### CHAPTER TWO.

All of my colonies wintered well except No. 6, which perished from too much coddling. Thus the spring count was three hives.

1. Golden bees No. 2.

2. Leather-colored Italians, Ferris hive. This later became Nos. 3 and 4, as I found it too heavy to work as one.

3. Hybrids with poor queen (No. 5).

No. 2 swarmed, so after the flow was on there were five colonies at work.

All were given section supers except No. 5, which produced all its honey in Hoffman frames.

Nos. 2 and 3 were shaken upon shallow combs at the time they were supered. The deep combs were left alongside until all bees had emerged, when they were shaken into their respective hives. Instead of going into sections at once, each of these hives filled the upper set of combs solid with white honey. This was removed, and the sections placed just above the brood, when the work went forward as planned. A story of foundation was put under all when the honey was removed. The honey was so easily produced, and was of such fine quality, that in July five more stands of bees were bought, as I hoped for a fall crop. In this I was disappointed. The crop was a little over 200 lbs. There were 92 Danz. sections, and the rest was extracted. There would have been about 60 lbs. more of extracted, but the heavy combs would not bear the strain of the extractor, so they were reserved for spring feeding.

All hives have sufficient stores to last till fruit bloom, and have young queens. No. 3 has superseded its queen, but both queens were in the hive at the last examination. If both live until warm weather comes, the plan is to use the mother as a breeding-queen, in a nucleus hive, and thus Italianize the five hybrid colonies last purchased.

#### THINGS LEARNED DURING THE SECOND YEAR.

1. Necessity of knowing one's own location, and of having the initiative in one's own business. Had I read before the season what I have later, I am sure we could have secured more honey. Being desirous of having all we produced of superior quality, we sacrificed quantity to an unnecessary degree. The fancy extracted sold for 30 cts. per lb., and the comb for 25 cts. per section, and in my own town I could have sold several times as much.

2. To keep the overstrong colonies busy before the flow, in drawing out brood and extracting combs.

3. To work every strong colony, not busy drawing combs, in two stories, preferably having the upper one of shallow combs. Should there be an early surplus, this will keep the honey above and removable when the time comes for section supers. The lower story will thus be all used for brood, and be extra strong at the right time.

4. Never to buy bees without careful examination before purchase.

#### PLANS FOR THE THIRD YEAR.

There are ten colonies, three in sectional hives, group one; four in ten frame, dove-tailed, group two; three in Danz., group three.

When I find out which of these hives I prefer, I intend to confine myself to one kind of brood-chamber, using the others for supers, but now anticipate much pleasure with the three small groups.

In order to get a maximum crop I shall avoid lifting and prevent swarming. Group No. 1 is to be worked somewhat as Mr. Scholl does with a trial of some of Mr. Hand's kinks. Group No. 2 I should have preferred to work according to Mr. Doolittle's plan, but could not get enough deep combs drawn last year to have two sets for each hive. I think early honey can be prevented from clogging the brood-chamber by putting on a half story of combs or foundation, just as soon as the strength will allow — if possible, before fruit-bloom. Then if these half-stories are filled with honey I can put two together, using Doolittle's plans and transferring to sectional hives at one operation. This will also prevent swarming and give increase.

One of the Danz. hives has two stories, both of which are almost solid with honey. In August, two colonies were united as per "Facts about Bees," as I intended to extract one story but found it impossible, as the combs were not wired and were insufficiently attached to sides and bottoms. These Danz. brood-bodies were among the five hives bought in July, and have so much drone comb that many frames will have to

be rejected. All these combs were made from starters by swarms, so my policy will be to use full sheets for swarms, either natural or forced.

As I do not know that I shall want any more Danz. brood-bodies, my intention is to work these colonies in the same way as group two, up to the time of the flow, when the first section super will be put on between the brood-chamber and shallow story, removing the latter when work is well started in super. This shallow story can be put under all on the bottom-board. I intend to try this to see whether the bees will carry up the unsealed honey it contains, as Mr. Hand and others say they will. Otherwise these shallow supers can be put on hives run for extracted, used for increase or piled up for future use, or to fill combs for winter.

As I can sell extracted honey of superfine quality, in small but dainty containers, at the same price as section honey, my intention is to run all hives for extracted at the end of the season, using section supers only during the rush of the clover flow, and have all sections fancy.

I intend trying the method used by Mr. Townsend and others of having extracting-combs on the outside of all supers. The new N super has frames exchangeable with shallow extracting-frames, and the Danz. super can use the shallow Danz. frames. If this plan does not prove desirable, the frames can be used in sectional hives or in extracting-supers.

Mr. Hand has strong colonies drawing out foundation in sections during fruit-bloom. Mr. Danzenbaker does the same, and also has the colonies, not needed to work on "go backs," at work drawing out sections for use the following season. I shall also try this plan.

The producers of honey by the barrel may like extracting from brood-chambers, doing without excluders and using all frames interchangeably sometimes for brood and later for honey, but I am yet to be converted to a belief that those methods are for the producer who desires the whitest and choicest of fancy honey.

Mr. Alexander proves that a home yard can be made strong much sooner by judicious feeding of dilute syrup, thus preventing the loss of bees which go for water and never get back. I have four Alexander feeders and two division-board feeders. I will use these and take notes; but outside feeders wear out the bees, invite robbing, and supply the neighbors, so I can not afford them.

I intend to follow out Dr. Miller's plans of records and examination of brood-chambers while swarms may be expected. He has shown conclusively that the hive that does not swarm gets the largest surplus of comb honey.

Alexander's tin tags to indicate age and value of queens are good enough for me, as is his way of getting increase when running for extracted and of saving weak colonies by putting them over strong ones. But I would

never unite at any season without a sheet of newspaper between. This is as sure as and easier than a screen which must be removed and thus disturb them later. I do not believe any other way of using two queens is practicable unless one is working the sectional hive.

Being unable to manage the towers that Mr. Ferris must build with his two-queen method I intend to work out a simplification of Mr. Hand's sleight-of-hand tricks. My season does not oblige me to complete sections in thirteen days, so I hope to raise comb honey and still keep alive. It is no wonder that he prefers queen-rearing.

Wenonah, Gloucester Co., N. J.

### BEE DISEASES IN CANADA.

#### A Case Where the Alexander Plan was a Failure; the M'Evoy Method Easier and Surer, and Less Expensive all Around.

BY J. L. BYER.

That article of E. M. Gibson's, page 125, tells exactly how the two methods of treating black brood work out in practice, as was proved in the work done by Mr. Warrington Scott, the first man in Ontario who had to battle with the disease. Although the colonies to be treated by the Alexander method were first made very strong, yet, after being queenless for 21 days, by the time the young force of bees came into the field of action the colonies were so weak as to be useless for the gathering of a surplus. While only comparatively few of the colonies so treated remained free from the disease, and the plan of removing all combs and shaking on to foundation was much more successful, Mr. Scott emphatically declares that, even if the Alexander method cured as many cases as the shaking plan, he would still prefer the latter method as being more economical in the end, all things considered. If a colony is made queenless right in the honey-flow, not nearly as good results will be obtained in the matter of securing a surplus as if the bees were thrown on to foundation. Indeed, there are quite a few who now claim that it pays to shake all colonies on to foundation, even if no disease is present; and personally we are inclined to accept this view provided a quick heavy flow of honey occurs right after the shaking and does not continue for more than two weeks or ten days. To be sure, it is well to remember that, as pointed out by both Mr. Gibson and the editor, locality may make a big difference in this matter of treatment, as in Mr. Alexander's section a lot of work could be done quite early in the season and still leave the bees in fair shape for the late flow that he so largely depended on. In a section where the only flow is from clover, entirely different methods must prevail if a surplus is to be obtained; and the shaking method, it seems to me, is the one for such places.

The modified plan as practiced by Dr. Mil-

ler reduces the period of queenlessness by quite a margin; but as our experience goes in the matter so far, it is not very likely that Mr. Scott will try any thing short of the more radical methods, in view of the pronounced failures experienced by using the full 21 days' term of queenlessness. Please do not think I am belittling Dr. Miller's efforts in the least, as I believe with all others that the plan has been a success with him; but as to such methods working out that way in Eastern Ontario at the present time—well, I for one sincerely wish that the remote success were a possibility.

In a footnote to a recent article of mine on this subject the editor does not think there is a difference in virulence, but rather inclines to the view that the difference in bees may explain matters. Regarding the virulence I can give no positive statement, as I have seen the disease in only one section, and can not give comparative evidence. As to the bees, it is only fair to say that nearly all in the affected district are blacks—regular old stagers that can sting a little quicker, and oftener, than any bees I have ever encountered. However, Mr. Scott's bees are now all pure Italians, and this past season an out-apiary of as pure stock as can be found on the continent was affected, and I believe they treated about 80 out of some 100 colonies.

While on this subject of black brood, I might say I am pleased to see D. M. Macdonald, of Scotland, also Editor Hurley, of the *Canadian Bee Journal*, making a vigorous kick against the term "European foul brood." The name has led to endless confusion, and why should we have any thing better (or worse) than the term "black brood," which all will understand? What's in a name, any way, so long as it expresses intelligently what we want to refer to? "Foul brood" is not such a high-sounding or scientific term by any means, and yet it answers its purpose finely. Why not drop "European foul brood" and say "black brood," and cut out all chances of confusion in the nomenclature of the two diseases? That the term does lead to confusion is evident in almost every bee-journal that comes to hand; and even Mr. Gibson, in his excellent article, gives us a hint in that line, as I believe no one who has ever handled genuine foul brood will think it is a possibility to cure the disease without destroying the combs. Therefore, instead of saying, as he does, that 21 days is not long enough for a colony to be queenless in order to effect a cure of American foul brood, better by far leave out the latter disease when discussing methods of curing black brood, as 121 days of queenlessness for a colony affected with genuine foul brood would be no more effective than 21 days, unless the longer term would give a chance for the wax-moths to get things cleaned up out of the way.

A BEE-LINE MAY NOT BE A STRAIGHT LINE.

As Raleigh Thompson points out, p. 125, a *bee-line* is not necessarily a straight line from the hive to a given point, even if we

all have heard the oft repeated phrase, "as straight as a bee-line." West of our home apiary, until the last two or three years, there was a strip of high woods about half a mile in width. At the other side of this woods there has always been a lot of alsike grown, and the bees invariably fly around either the south or north end of the woods while going to and from the apiary to the clover-fields. During the flow of honey, if one went close to the woods on the east side no bees could be seen or heard; but on going toward the north or south ends they could be seen by the hundreds, although by taking these courses at least a quarter of a mile more would have to be traversed as compared with a direct course over the tree-tops. At the Cashel yard there is a tall row of spruce-trees directly north of the bees, running east and west; and off at one side of the yard a bit, there is an opening where a few of the trees did not grow well. All the buckwheat grown in reach of the bees has generally been directly north; and many a time have I noticed the bees going and coming through this opening in such swarms that it really seemed as though they would knock against one another in their flight. Really it is wonderful to see the bees from about 100 colonies working on buckwheat during a heavy flow, when practically all of them are going through an opening only a few feet wide. The point I wish to note is that the bees, instead of rising and going directly north in the direction of the buckwheat, rather preferred going west a short distance and then making a tack so as to avoid flying so high over the tree-tops.

While I am inclined to believe that bees are enticed toward nectar by scent, yet I rather doubt that the circumstance related by friend Thompson *proves* the matter. Two years ago there were hundreds of acres of alsike near us, some of it not more than two rods away from the bees, and yet for some reason there was no nectar in the blossoms. Last season we had a tremendous flow from alsike for six or seven days; and after that, although the clover was in bloom for two weeks more, yet hardly any more honey was secreted. How do we know that the field of clover mentioned by Mr. Thompson was yielding nectar previous to the day the bees were noticed working on it? Even if the bees were noticed around small patches near home, yet that does not prove conclusively that the field in question was yielding, as we have often observed that the bees would be working heavily on one field when possibly some other field nearer would have very few bees. Our only theory has been difference in soil conditions, as, generally speaking, the heavier clay soils do better in clover-honey production than do the lighter ones. However, I will admit that it *looks* as though the bees in Mr. Thompson's case did scent the nectar; yet I repeat, it is not a conclusive case by any means.

SHEEP TO KEEP THE GRASS DOWN.

The editor's advice to S. E. Williams, page 124, regarding the good work of sheep in an

apiary for the purpose of keeping down grass is sound, although a word of caution is necessary as to how the hives should be placed to avoid having them turned over on their sides.

At one of my yards the bees are wintered in rough cases, and then the hives are taken out in the spring about fruit-bloom time, and placed in pairs on stands six inches high. As long as the bees are in the cases the sheep in the yard are a fine thing; but as soon as the hives are on the summer stands after being taken out of the packing, I have always considered the sheep a bit dangerous to have in the yard. However, last spring, contrary to my advice, the owner of the orchard wherein the bees are situated let a flock of sheep into the yard about the first of June, thinking no harm would result. As a matter of fact, the same thing had been done in previous years a few times with no trouble. However, it was the old story of "the pitcher that off goes to the well, etc.," again; and when I went out to the apiary a few days after the sheep had been let in the yard again I found one of my best colonies with the hive lying over on its side, the cover off, frames all jammed together, and most of the brood dead. The hive was righted and frames adjusted, and the bees, depleted in numbers, went to work to make the best of a bad job; indeed, it was about as bad as it could be; for before leaving the yard in the afternoon the queen was found dead, dragged out at the entrance. Of course, that meant no surplus for the season from that colony; and as that apiary averaged over 150 lbs. per colony, we naturally were sorry that we had not cut all the grass ourselves. If the hives are close together the sheep will often get to rubbing themselves, and gradually work in between the hives. This process we have noticed more than once, so the remedy would obviously be to place the hives singly or else so close that not even the head of a sheep could get between. Certainly the presence of sheep in a yard is a nice way to keep the grass down, provided it is so arranged that no hives can be upset.

Mt. Joy, Ontario, Canada.

## DIRECTIONS FOR "SPLINTING" FOUNDATION.

BY EMMET B. KIBBE.

I want to put some foundation in Jumbo frames, and not have it sag or buckle if I use medium brood. Will it be best both to wire and splint it? If so, shall I draw the wires taut? Ought I to wire and imbed the wire first, then apply the splints?

Must I have splints long enough to reach to the bottom-bar?

Cincinnatus, N. Y.

[We referred these questions to Dr. Miller, who replied as follows:]

The object of pressing splints into foundation in brood-frames is to prevent buckling, to prevent sagging and stretching of the cells in the upper part of the foundation, and especially to secure combs built clear down to the bottom-bars. The splints are placed perpendicularly in the frame, and are about  $\frac{1}{4}$  inch shorter than the distance between top-bar and bottom-bar. That  $\frac{1}{4}$ -inch space is merely for convenience in putting in, and it does not matter whether it is at the top, at the bottom, or divided between top and bottom.

As the bees are inclined to gnaw at the bottom of the splints, especially when little honey is yielding, some use five-inch splints, putting them at the upper part. This secures against the stretching of cells at the upper part, but with these short splints there must be wiring to prevent bagging at the lower part.

The foundation is fastened to the top-bar the same as when no splints are used, and the foundation is cut to fit close up to each end-bar. A split bottom-bar may be used, allowing the foundation to come down and be fastened between the two parts. One part of the bottom-bar is nailed on when the frame is made, the other after the foundation is in place. Of course the foundation is cut large enough to reach down to the bottom of the bottom-bar. Then at the middle a small nail driven through both parts of the bottom-bar pinches them together, holding the foundation in place firmly.

Instead of the split bottom-bar, the ordinary single bottom-bar may be used. In that case the foundation must be cut to make a close fit at the bottom, and melted wax must be run along the edge of the foundation to fasten it to the bottom-bar. Even if the split bottom-bar be used, it is better to use the melted wax so as to prevent the bees from starting to gnaw. The only object of the split bar is greater convenience in making a fit at the bottom, for with it there is no need to be exact about cutting the bottom of the foundation. After the work is done, the single bar is just as good as the split bar—perhaps better.

To drive the moisture out of the splints and to fill their pores with wax, throw them into wax boiling hot. They will froth up with the air and steam driven out of the splints. When all frothing ceases, take them out of the wax and keep them stirred as they rapidly cool, so they will not be stuck together.

When ready to press the splints in place, the frame with foundation is put on a board the same as for wiring, the board being large enough to fit rather loosely inside the frame, with stops on the edges of the board to allow the foundation to be in the middle of the frame. A heavy black mark is made on the board at the place where each splint is to be laid, the black mark showing through the foundation. The mark will show more plainly if the board be painted white, or if white paper be pasted upon it.

In a brood-frame of usual length a splint is placed at each end about  $1\frac{1}{2}$  inches from the end-bar, and another in the middle of the frame. Then, if medium brood foundation is used, a splint is placed midway between each end-splint and the splint at the center. But if light brood foundation is used, two splints will be used in place of each one of the last two splints, the space being equally divided. Thus it will be seen that for medium foundation there will be five splints with spaces between them of about  $3\frac{1}{2}$  inches; and for light foundation seven splints with spaces between them of about  $2\frac{1}{2}$  inches.

A few splints are thrown into a shallow dish of wax kept only hot enough to be liquid (if boiling hot the splints will melt their way through the foundation), and one by one each splint is lifted with a pair of pliers and laid in place, while a helper presses each splint into the foundation by means of a little board with an edge  $\frac{1}{4}$  to  $\frac{3}{8}$  inch thick, this edge being kept wet.

Another way that is possibly better, but has not been so thoroughly tried, is this: Instead of using a pair of pliers pick up the splint with the fingers, holding it by one end; dip it into the hot wax as far as possible without touching the wax with the fingers, and then lay it in place, putting next the top bar the dry end, which is held in the fingers. The upper end may not be so well imbedded as if dipped in the wax; but bees are not much inclined to gnaw at the upper end. In this way there is less harm from having the wax very hot, and one can handle the splints more rapidly with the fingers than with the pliers.

For ordinary brood-frames there is no object in having wiring when splints are used. With frames of unusual depth there is a possibility of the foundation bellying out to one side, so it may be well to have a single horizontal wire drawn taut midway between top and bottom, or else two wires some three inches apart, the wire being imbedded before the splints are put in. For extracting-frames, there will be less dan-

ger of combs breaking out in the extractor while they are new if wiring be added, if, indeed, it be thought advisable to use splints at all in extracting-frames.

It is important to keep in mind that bees have a strong inclination to have a passageway between the lower part of the comb and the bottom-bar. If a frame of splinted foundation be given when bees are doing little or nothing, the bees will be pretty sure to dig away this passageway, using the wax gnawed out to help in the upper part of the frame. So such frames should be given to the bees to be drawn out only at a time when honey is yielding well. In an upper story the bees do not care so much to make this passageway.

C. C. MILLER.

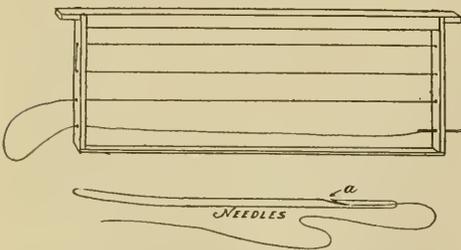

## THE METCALFE FRAME-WIRING NEEDLE.

### Some Hints about Wiring Frames.

BY O. B. METCALFE ("THE N. M. CHAP").

Having several thousand brood-frames to put together and wire last spring I set about getting up some contrivances to aid in the work. The accompanying cut shows my needle for wiring frames. The tip end of the wire is drawn tightly into the small slot shown at *a*, where it wedges in so tightly that it may be pulled in two before it will slip out. The needle automatically grips the wire at the very end, and so that the wire may be drawn by the needle itself.

When the wire has been threaded through all the holes, the very tip end of it may be tightly wrapped four or five times about the last nail by simply holding the wire just inside the frame firmly with the left hand, while with the right the needle is twisted round and round the partly driven nail, the wire being forced to feed out through the slot as it wraps around the nail. As soon as one gets well on to the trick, the end of the wire will be wound so closely up to the nail as to leave no trace of it after the nail is driven up. The operator does not get his fingers pricked while doing it, and nothing is left to prick fingers in the future.

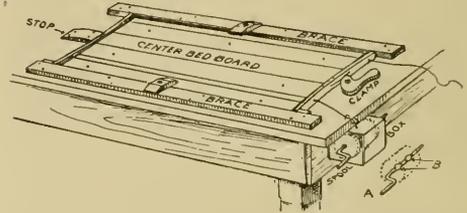

I made some of these needles last season, and gave them to my neighbor bee-keepers. They reported that they were such a boon to them that they could not get along without one, and I know I shall never wire as many as fifty frames without one, even if I have to stop and make it.

Some credit is due my partner, H. L. Parks, for perfecting this needle. I at first made the slot right at the end of the needle; and after sticking the doubled-back end of the wire in his fingers a few times he suggested that I make the slot further up the needle so about a quarter-inch of wire could be turned

back without extending past the needle. The suggestion was a good one, and, so far as I can see, perfected the needle.

### A FRAME-HOLDER FOR CONVENIENCE IN WIRING.

Next in order of contrivances I made a frame-holder for holding the brood-frames while wiring them. Any one may make one of these by a study of the illustration.

The small wooden eccentric, when it is turned toward the frame, will crowd the frame against the small block opposite, and the end-bars will be slightly sprung in. If I remember correctly, I read this plan of springing in the end-bars in *GLEANINGS*; at any rate, it is not original but worth repeating; for it leaves the wires tightened better than any other method.

Make the small wooden box just a little larger than necessary to hold a spool of wire. Put the spool in it and bore through the sides of the box with a small bit so the bit will pass through the hole in the spool and on out the other side of the box. Next get a small iron rod of a size to go loosely through the hole in the spool, and about 14 inches long. At two points, about 2 inches apart on the rod and about 2½ inches from the end, mash it with a hammer until it will not quite go into the spool. File the edges of the flattened places sharp. Put a spool of wire in the box, and force the flattened places through the hole in one side of the box, and far enough into the spool so the end of the rod will pass out the hole in the opposite side of the box. Bend the remainder of the rod to a right angle twice, making a small crank. Nail the box under the table so the wire will feed out just right to enter the hole at the top of the right-hand end-bar, and so the little crank will be handy to turn with the right hand. Drive a staple in the edge of the table for the wire to pass up through, and you are ready to wire frames.

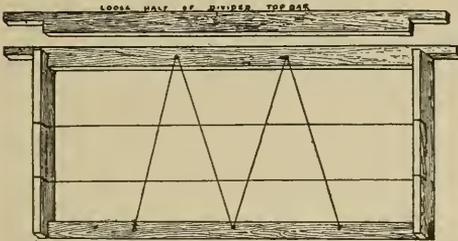

When the wire has been passed through all the holes and fastened to the nail, and the nail driven up, as is usually done, take hold of the little crank and begin to wind, helping the slack along with the left hand. When the wires seem well stretched, catch the wire just outside the frame, and, holding it tight, let go the crank; wrap the wire four times about the nail driven for that purpose; drive the nail up well, and again go through the same motion you did to wrap the wire around the nail. This twisting will break the wire off close under the nail head, and you will have a well-wired frame with no sharp ends to stick fingers in the future.

Mesilla Park, N. M.

# HEADS OF GRAIN FROM DIFFERENT FIELDS

## A FRAME WITH A TOP-BAR IN TWO PIECES.

For quite a number of years I have been using a frame of my own invention, which I think beats any thing on the market for ease of wiring, fastening

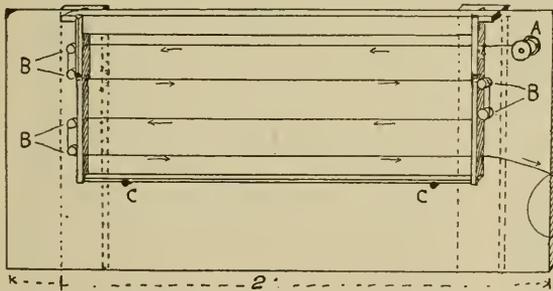

foundation, and especially for replacing damaged combs of foundation. The top-bar is in two pieces, the loose piece being nailed to the other after the foundation is put in place. I formerly nailed the end-bars also to this loose piece; but for replacing damaged combs, etc., I find it more convenient, and just as strong, if the end-bars are not nailed to the movable piece. The double wiring, as in the illustration, shows how easily and quickly either horizontal or vertical wiring may be done.

Pittsfield, N. Y.

GEO. A. HUMPERT.

## PREVENTING THE WIRE FROM CUTTING INTO THE END-BARS.

Wire is somewhat springy; and as soon as a short length is removed from the spool it forms loops. The loops are liable to make kinks, and these break when the wire is drawn tight. When the end on the spool is released, the wire promptly unwinds enough so that

several dozen turns drop off the lower end of the spool because of this same springiness or elasticity. Once off the spool, the tangle begins.

Drawing the wire through the frames also has its difficulty, as the wire cuts into the wood of the end pieces where it turns the corner to go from one hole to another. A roller at the end of each span of wire just outside the end pieces, and tangent to a line drawn through the holes, was the apparent remedy; but while reflecting on how to make the rollers I remembered how easily the wire slides around a broom handle which I had used for straightening short bent pieces of wire, and found this a good substitute for rollers, when arranged on a board as shown in the attached plan.

The board is 2 feet long and 13 inches wide, underneath which are fastened two three-inch cleats which serve to stiffen the board and hold the pegs firmly. The pegs are of maple, and project 1 1/4 inches above the surface of the board. The two rows are 17 inches apart, and the pegs are shaved off on the inside so as to hold the frame more firmly. A three-inch nail is used for a spindle for the spool, and four one-inch finishing nails, driven in the lower flange of the spool, keep the wire from dropping off and catching on the spindle. A three-inch disk of tin, nailed on the lower

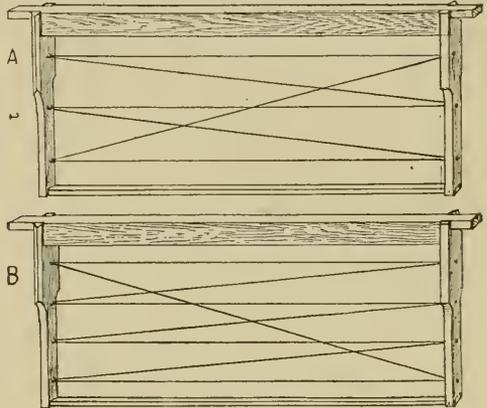

end of the spool, might serve the same purpose. After the wire is drawn through the frame and the end is made fast, the frame is lifted from the board, slipping the wires from the pegs, when the spans can be tightened and the wire made fast at the end next the spool and then cut off without waste.

Elyria, Ohio.

W. J. M.

## NAILS BENT IN THE FORM OF HOOKS INSTEAD OF HOLES IN THE END-BARS.

Nearly every one runs the wire through the end-bars. This is surely a laborious manner in which to get the wire in the frame. I simply drive three slender nails through each bar, and with round-nosed pliers turn up the points on which to hook the wire. This makes five wires in the center, where the most sagging occurs. The wires must be drawn tight. If left slack, of course the foundation will sag. You will observe that the wires are too close together for the foundation to buckle. If not close enough, use four

nails instead of three. I hear some say that this is too slow—takes too much time and labor. I will venture this assertion: I can drive and bend the nails, run the wire on the hooks, fasten the foundation with melted wax and brush, twice as fast as I can by running the wire through three or four holes in each end-bar; the imbedding of the wires, only a trifle more. The wire from top to bottom hook is for a brace or stay to overcome the tendency of the other two or three diagonal wires drawing the frame out of square. With this the frame is held rigidly square by using a brace in the frame when drawing the wires. It takes but little more wire than the usual way. None is lost running up and down the end-bars. All is in use, and no foundation will sag or buckle if the wires are tight.

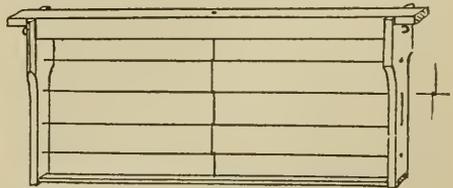

Corona, Cal.

H. M. JAMESON.

[See answer to C. Pennock on next page.—ED.]

## HORIZONTAL WIRES SUPPORTED BY ONE VERTICAL WIRE.

My combs are perfect. There is no sagging of the foundation or bottom-bar, and no drone-cells. I punch

a hole in the center of the top and bottom bar; run a wire through; fasten wire with nail the same as horizontal wires are fastened; give one turn around each horizontal wire, then run it through the bottom-bar;

draw fairly tight (if too tight it is liable to cut the wires); then fasten. It does not bother when putting in the foundation.

Bellvue, Colorado.

CHAS. E. PENNOCK.

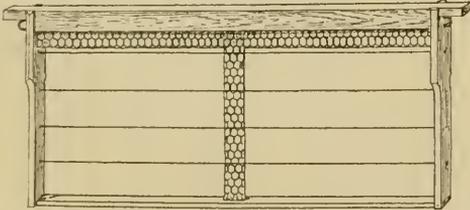

[Some years ago we tried various schemes of cross-wiring. We finally settled on what was known as the Keeney, which is a good deal the same as that shown and described by H. M. Jameson on the previous page. The difficulty with all intersecting wiring is the tendency of the foundation to bulge or buckle in the triangles formed between the wires. At the precise point where the wires intersect, there will be no sagging; but as the foundation is drawn out, the portion above the intersection has a tendency to bulge, and the result is a slightly uneven comb surface.

The best scheme of wiring is a series of vertical wires without intersections; but with ordinarily thick top-bars this does not seem to be feasible, especially with those who use the wedge-and-groove plan. We finally adopted the four horizontal wires—the wires being threaded through the end-bars. This form of wiring only partially overcomes the sagging of the foundation while it is being drawn out into comb. The portion one inch down from the top-bar (if light-brood foundation is used) is liable to have elongated cells. These will be filled with honey, while the portion below will be filled with brood that will have normal-sized cells.

Dr. C. C. Miller, to overcome this, put in vertical splints. Under some conditions, and with some beekeepers, the plan leaves nothing to be desired. Under other conditions it does not quite fill the bill.

We have had in mind for some time back a scheme for incorporating wires in foundation after it is run through the rolls, the wires being inserted on a vertical line. This plan will still necessitate wiring the frames as now, as no scheme of putting wire in the foundation at the factory will answer unless those same wires can be secured to the top and bottom bars of the frames; and no Yankee or other genius thus far knows how to do this without making the cost too great. When running extracting-yards it is very important to have the wires secured permanently to the frame. A scheme of wiring that merely prevents stretching or sagging of the foundation is a long way from being satisfactory. Years ago we tried running wires in along with the sheet of wax as it went through the foundation-mill. Mr. E. B. Weed worked on this problem for some time, but gave it up in disgust. While it may work with flat-bottom foundation, no feasible plan has yet been presented to make it work on *natural-base* foundation. But if there is any demand for vertical wires in ordinary brood foundation the article can be supplied. In this case the wires would be incorporated by means of electricity after the foundation has been run through the rolls.—ED.]

I ran short of foundation when I needed it most, so I economized by putting a vertical strip one inch wide in the middle of each frame, and also used the one-

inch starter at the top. My frames were already wired, so I imbedded the wire where the vertical strip of foundation crossed it as shown in the diagram.

The bees built straight firm comb in the frames so treated, and I was unable to tell those frames from those in which I had used full sheets at extracting time.

Of course, I do not claim there would be any thing saved by this plan in the long run, for no doubt I might have had more honey by using full sheets.

Colegrove, Pa.

R. A. WILLSON.

[This plan is perfectly feasible under some conditions and some seasons of the year; but in many cases one would get a large amount of drone comb.—ED.]

#### BRIEF REPORT OF THE MICHIGAN STATE CONVENTION.

After the secretary made his report a discussion was opened on membership fees, whether it was policy to

remain in affiliation with the National, etc. It was pointed out that the extra 50 cts. which was paid to the National could be used to good advantage in pushing the work of increasing the membership of the Michigan Association, and also in better advertising the booklet which has been a direct means of selling the members' honey. On the other hand, it was advanced that we should stay by the National in order to get the benefit of its protection in legal matters, and also on general principles. It was finally decided to remain as before; but an extra assessment of 50 cts. per member was levied for the Michigan, which virtually placed the membership in the Michigan at \$1.00 a year with an extra 50 cts. to go to the National. This gives the members membership in both. Another important action was in having the membership in the Michigan expire Jan. 1 each year.

The question of wiring frames to prevent sagging came up as a result of a paper prepared by General Manager N. E. France, of the National. Some lively discussion followed. The result was that the Association agreed that, no matter how one wires, there will be sagging as long as the foundation is made as now, with the cells running parallel with the top-bar. The following resolution was passed: "Be it resolved by the Michigan bee-keepers in convention assembled, that the manufacturers of comb foundation be asked to consider the question of making brood foundation so it will hang just opposite the way it is now made, the object being to prevent sagging."

The marketing of honey by cooperative methods came up for some lively and interesting discussions. During the past six years the association has been publishing a booklet giving the names of its members, and statistics regarding the amount of honey produced, and this has been a great help in finding markets. This year it was advertised in three bee-journals, and as a result it was sent all over the United States. One bee-keeper who produces at least 10,000 lbs. of honey annually, stated that he could sell ten times as much as he can produce, and gives the credit to the booklet. This year there will be 1500 published, and they will be even more widely distributed than before. This will probably be the extent of the cooperative efforts in selling this year, excepting information which will be given the members by the executive board regarding supply and condition of markets. Another year, however, may see an advance along this line.

The program as formerly published in the bee-journals was carried out, the papers of those not present being read by the secretary. Visitors from outside the State were Geo. W. York, of the *American Bee Journal*, and L. W. Boyden, of The A. I. Root Co. Mr. York read a paper entitled "Honey, its Marketing and Staple Use." Mr. Boyden contributed some valuable suggestions on the advertising of honey, among them being demonstrations at pure-food shows.

The former officers were reelected, remaining as follows: President, L. A. Aspinwall, Jackson; Vice-President, E. D. Townsend, Remus; Secretary-Treasurer, E. B. Tyrrell, 230 Woodland Ave., Detroit.

The next convention will be held in Grand Rapids.

Prizes were awarded as follows on the exhibits made: Best 10 lbs. of comb honey, first, C. S. Foote, of Ridgeway; second, L. C. Wheeler, Barryton. Best 10 lbs. of extracted, first, A. D. D. Wood, Lansing; second, L. C. Wheeler; 3 lbs. of extracted containing least water, first, L. C. Wheeler; second, A. D. D. Wood. Best 10 lbs. beeswax, first, A. D. D. Wood; second, J. H. Peters, Detroit; third, L. C. Wheeler.

Hon. Geo. E. Hilton will represent the association at the State Legislature in reference to any foul-brood legislation, and the executive board will appoint a representative to meet with the National at its next meeting.

Detroit, Mich.

E. B. TYRRELL, Sec.

#### HOW TO REQUEEN IN EARLY SPRING.

What would you advise a beginner to do when he finds one of his colonies queenless in early spring? Omega, Okla., March 14.

N. D. DICKEY.

[In almost every case you will find that there will be one or more other weak colonies in the yard having a queen. If any colony, strong or weak, is queenless, unite it with one of these colonies having a queen. If it is a little early in the spring we would advise putting two colonies together, placing them in the cellar and keeping them there for about a week, and then set them out permanently on their summer stand. But we would place such colony on the stand occupied by the stronger of the two, because some bees will return to their old stand. These can be collected in an empty hive having a dry comb, and placed where they belong.—ED.]

A REPORT FROM ONE WHO USES AN AUTOMOBILE IN  
OUT-APIARY WORK.

I was pleased to read and note what you have said in GLEANINGS on automobiles. I have been impressed with the idea that the automobile is what the outyard man wants, so that I could not rest until I succeeded in finding one that I could buy, about the beginning of September last, and which has fully demonstrated the advantages looked for. When I have taken a team to a yard 20 miles away it has taken all day; but when I took the Runabout I had eight hours to work, "or more if wanted." I took my exhibit to and from our county fair, including a new demonstration cage.

We simply run the machine under a large apple-tree, jump off, and go to work. Well, I thought that *that* machine ought to be credited with my extra three or four hours' time that morning, and also with half the expense of a team. I value it at \$200. I have carried five hives of bees as well as other things, and I consider there is nothing their equal for carrying bees. Ease and quickness are what are required for that. I think I can do about double the amount of peddling honey in a given time with it over the old way.

My machine is only seven-horse power. I want one about sixteen-horse power, and more room for carrying supplies or bees.

I shall look forward with much interest to what you will have to say about them from time to time. Perhaps you could get up such a machine. I should think you could sell any number of them, as they would be just what the farmer as well as the bee-keeper needs, for it looks to me as if it would practically bring the farmer 40 per cent nearer market.

Manistee, Mich., Feb. 20. WALTER HARMER.

SWEET CLOVER COMING TO BE RECOGNIZED BY THE  
AGRICULTURAL PAPERS.

I am making considerable headway with sweet clover in my State. One year ago no farm journal would tolerate the idea of advocating the sowing of *Melilotus alba*; but now, if you read *Wallace's Farmer* you will notice that they advise farmers to sow it under certain conditions, saying it should be taken on trial by all farmers. It begins to look now as though *M. alba* were to play a prominent part on every farm in the United States, both where alfalfa is grown and where red and alsike are depended on.

Much good has come from Henry A. Wallace's visit to my field last fall, and that is why he recommends its use as a pasture-plant, and the coming summer I hope to demonstrate its value as a superior hay crop, just as I have done as a superior pasture legume.

THE YELLOW VARIETY PROMISES WELL.

I am harboring a strong hope that the yellow variety may prove to be of great value to sow in the corn at the last plowing, and then to be pastured the following season or be plowed under the last half of May. If this proves to be good it will mean more to the corn-belt farmer than any thing of the kind that was ever brought to light. That is why I want this yellow seed. Yellow sweet clover grows two feet high here by the 16th of May, and could be turned under; and what a fertilizer it would make, and all in time to plant to corn! or if sown with timothy it would make a splendid pasture; or knock down the stalks, and with a binder cut it for seed. It is a proven fact that sweet clover is the best to feed to stock, and that it contains more of the essentials than any other clover. Doesn't the future look bright for sweet clover?

Maquoketa, Ia., Feb. 7. FRANK COVERDALE.

IS IT TRUE THAT WINTERING AND BREEDING UP IN  
THE SPRING ARE WEAK POINTS IN SECTIONAL  
HIVES?

I am glad I read Bro. Holtermann's report of the Chicago Northwestern convention, p. 45. Here I've been keeping bees in sectional hives right by the side of other kinds of hives for a quarter of a century, and do not know yet that wintering and breeding up in the spring are weak points in these hives.

Regarding the decision by voters of the convention as to what constitutes an eight-frame or a twelve-frame hive, I feel sure that, upon a more mature deliberation, the decision would be reversed by the same jury, for no one can deny that when a super is temporarily used as a brood-chamber over an eight-frame hive it becomes for the time being a sectional hive of 12-Langstroth-frame capacity with all the advantages of a sectional hive, which advantages should be apparent to every thinking bee-keeper.

Where is the economy in having a fixed twelve-frame brood-chamber for the bees to shiver in all win-

ter and spring when they would be so snug and comfortable in an eight-frame body? Why not make them of twelve-frame capacity when that capacity is needed (during the breeding season), by adding a super?

Birmingham, O. J. E. HAND.

NUMBER OF COLONIES NEEDED TO SECURE CROSS-  
POLLINATION OF FRUIT.

We should like to know if you have any data giving the number of stands of bees necessary to insure pollination of fruit-trees in orchards. We should like this estimate based on acreage. We know this is a subject that is very hard to arrive at any definite conclusion on; but we should be interested in having any report you could make us.

PORTLAND SEED COMPANY.

Portland, Oregon, March 9.

[There is no absolutely accurate data giving the number of stands of bees necessary to insure pollination of fruit-trees in orchards. Progressive fruit-growers, however, are asking to have bee-keepers put in their orchards somewhere about ten or a dozen colonies each. If the orchards are very large, such as are in California, Colorado, or possibly in Oregon, a much larger number would be required. We would rather err on the side of having too many than too few bees. No trouble has been experienced where there are as many as 100 colonies to one small orchard, that is to say, that number does not seem to overdo it. Whether a dozen colonies in the same orchard would do the work just as well, we can not say.—ED.]

SWARMING OUT AFTER SHAKING ON FOUNDATION.

On page 81, Feb. 1, Mr. Percy Orton says, "Don't shake bees on to foundation alone, as over half will swarm out." I shook fifteen colonies on to foundation and but one swarmed out, that one having less than a quart of bees. I could hardly blame them. This is not "ancient history" but modern, having occurred last season. I shook them in the evening after dark, giving them all night to think it over. Perhaps that makes a difference; who knows?

Canon City, Col., Feb. 9.

W. G. WRIGHT.

[If bees are shaken off on to foundation during the middle of the day, say from 10 to 2 o'clock, there is some danger, especially during the swarming season, that they will swarm out. If they are shaken out at or toward night, they will cool off by morning, and probably by that time be ready to start housekeeping anew.

Years ago, when we shook on to foundation to cure foul brood in our yard, we always shook toward night, or just as it was getting dark. We treated in this way in all something like 80 colonies. There was not one of them that swarmed out, so far as we now remember; and the bees went to work the next morning building the foundation into comb.—ED.]

DO FIELD PEAS YIELD HONEY?

I write to know if bees gather honey from the common varieties of field peas. Last spring was very unfavorable. It rained three to four times a week, and the bees did not gather any honey; but in August we had several fields of peas in bloom, and the bees worked on them all day. Whether they were gathering pollen or honey I don't know.

Calhoun, Ga.

BOYLE DILLARD.

[Our impression is that common field peas do under some conditions yield honey. They belong to the same general family as the locusts; and there is no reason, when conditions are right, why they should not yield some nectar. If any one has any evidence to offer we shall be pleased to hear from him.—ED.]

A HONEY-BANQUET.

A year ago at the State fair we organized the Shawnee Co. Bee-keepers' Association, and now we have 30 members. This winter we met with the Kansas State Bee-keepers' Association, and we had a good time. I think if every county could have a county association for home encouragement, and then send a delegate to the State association it would encourage the industry and be a great help to all bee-keepers. Of course, here in Kansas the bee industry is new; but it is fast coming to the front, and Kansas is bound to be a grand bee State, as there is much alfalfa raised here. At the close of the meeting we had a honey-banquet. Everything was made with honey, and honey in all forms was on the table. We had an observation hive with bees in it for a center piece, and everybody went home well pleased and happy.

Topeka, Kan.

J. P. LUCAS.

#### SPRING FEEDING BY PLACING COMBS OF HONEY IN THE HIVE.

After studying what has been written about spring feeding I should like to try a plan recommended by Mr. Gray, of England, in *GLEANINGS* for 1908, p. 1200. He advises placing a frame of honey in the center of the brood-nest about the first of May, and then, fourteen days later, giving them two other frames; and after other fourteen days, two more. I should like to hear from any one in this country who has tried Mr. Gray's plan and can tell how it works.

#### TWO COLONIES IN ONE HIVE.

I have a few colonies of bees in the cellar that are weak. When they fly in the spring I intend to put two colonies into one hive with a division-board between them. The division can be made of veneer tacked to top and bottom cleats. This arrangement will conserve the warmth.

Ridgewood, N. J.

WM. LEITCH.

[England has a much milder climate than most sections in the Northern States. Putting a comb of honey in the center of the brood-nest by May 1 might be too much of a good thing. In many localities it would be far better to put the comb of honey at the side of the brood-nest by May 1. Later on it might do to put it in the center. Before a brood-nest is tampered with very much there should be settled warm weather.—ED.]

#### SKUNKS KNOCKING ON THE HIVES.

I have been experiencing considerable difficulty in keeping the triangular entrance-blocks in place. I had the same trouble during previous winters, but worse this one. I could not believe they had been worked away by the wind so frequently, for on many occasions I had found them displaced when I knew it had been comparatively quiet. I became suspicious that chickens, rats, or some other animal was responsible, and was on the point of setting a trap. Last night, about nine o'clock, my wife discovered something knocking at one of the hives. This hive rests on pieces of brick about two inches from the ground. It was covered with a light box for shade. Stealing quietly to the hive I listened for some time to the drumming, which was as regular as any bee-keeper ever produced. I finally discovered that the drumming was beneath the hive. By stooping I could discern the animal by the bright moonlight, and every little while it would poke out its head. A lantern and a rifle were brought, and with the added light of the lantern the drumming still continued. The animal would pause and stick out its head, and I took advantage of this exposure and gave it a ball. I do not know how it could have produced this drumming unless with its head. The bees did not seem much disturbed. They had probably been drummed in this manner so frequently that they were used to it. I suppose the purpose was to cause the bees to fill themselves with honey and then attract them to the entrance by scratching, where they could be caught.

Geary, Okla., Jan. 28.

N. F. GARDINER.

[Skunks may have learned the trick of bumping on hives to draw the bees out at the entrance. Say! you didn't tell what happened after you shot the skunk. We have been informed that, unless the shot instantly kills or paralyzes, the animal will scent up the neighborhood. We infer that you made a good shot.—ED.]

#### HULLED SWEET-CLOVER SEED SETS AS QUICKLY AS ALFALFA, ALSIKE, ETC.; THE HULLED REQUIRES SIX MONTHS.

The articles in *GLEANINGS* on the subject of sweet clover are very interesting. I bought a few pounds of The A. I. Root Co. in the fall of 1909. The yellow was hulled, the white was unhulled. I sowed both varieties in September. The yellow hulled seed came up in ten days, but the white showed no life. On page 828, June 15, 1907, J. A. Green says the white hulled seed came up very promptly, while the yellow unhulled came up best the following spring. I think our combined experience shows that hulled sweet clover seed of either variety will germinate just as quickly as alfalfa, alsike, or any of the clover family, while the unhulled seed requires six months, or time to rot the hull before it comes up, thereby removing the ban that has been following sweet clover—that is, that it invariably takes six months to germinate.

As clover honey granulates quite readily the apiarist is fortunate if he lives where galleberry (holly), mountain sage, or snowdrop grows. The snowdrop grows on the open hills or in dense forest growth in my lo-

cality. It is a fine-growing shrub, never over four feet high, with a small pink bell-shaped flower that produces an abundance of water-white honey in June. The seed is produced in white berries that hang on all winter. I have a bottle of this honey mixed with clover three years old that has frozen repeatedly, and has just commenced to granulate.

Fraser, Idaho, Feb. 16.

F. F. GEORGE.

#### A LEGAL CONTROL OF BEE TERRITORY WOULD BE UNCONSTITUTIONAL.

Referring to the article on page 41, Jan. 15, about the control of bee territory, I can not see why a bee-keeper should claim exclusive right to any territory any more than a person engaged in any other business. Has a physician or a lawyer an exclusive right to any territory, to the exclusion of others in the same profession who may choose to enter that locality to try to make a living? Even though the meat or grocery business of a certain place is overdone, who shall claim that no one else has any right to start in the same business there? Because a certain dairy can supply all the milk demanded by a certain community, does that fact forbid any one else starting a dairy if he so desires? If the bee-keepers of Imperial Valley have formed a "trust" to keep out all intruders, how are they any better than the Standard Oil Co.? Do not their methods savor somewhat of those of the Western Federation of Miners? So far as legislation to give any bee-keeper control of certain territory is concerned, I think it would be unconstitutional from the very bottom, and contrary to the rights of every free citizen. I regard bee-keeping as similar to any other business. The man who starts it does so to make it pay, ordinarily, and I can not see why laws should be passed to protect him especially against any one else who might wish to engage in that business in the same locality, any more than that laws should be passed to give a blacksmith control of all the territory within a given number of miles from his shop, to the exclusion of all other prospective blacksmiths. Dr. Miller says there is no conflict about a cow-pasture, and asks why there should be about a bee-pasture. I grant the first part. As a rule the owner of the cows owns the pasture also; but suppose those cows had wings and could fly all over the country, feeding where they like. I fear that then there would soon be trouble. In the same way, if the owner of an apiary owned all the land within the limits of the bees' flight there would be no cause for trouble; but such a condition is almost unheard of, and the bees must pilfer from many land-holders.

I do not in any way favor the Australian system unless the payment is made to the owners of the bee-pasture. What right, moral or otherwise, has a State or county to collect revenue by granting to one person the privilege of allowing his bees to steal nectar from the flowers belonging to others, and forbidding such owners to keep bees to gather the nectar from their own fields and orchards?

A man may plant a great fruit-orchard or tract of alfalfa, and establish a few hives of bees for insuring fertilization. Along comes Mr. Special Privilege, bee-keeper, and says, "Here! you must not keep bees, for I have bought the right for this locality."

"But," says the orchardist, "it is my land, my orchard, and therefore I consider it my honey if my bees gather it."

"No," says the other, "you must give the honey to my bees, for I have bought the privilege, and you would be interfering with my business."

What sort of justice is that, to compel a man to give the nectar from his orchards and other flowers to some "protected" bee-keeper? Dr. Miller's comparison of stock-raising and bee-keeping will scarcely stand; for not much stock is allowed to range wholly free as are bees, but in most cases it is kept within certain definite limits.

Fort Casey, Wash., Feb. 17.

ERLE SARGENT.

#### QUESTIONS ON BEE DISEASES.

I have received lesson 13. Please send me lesson 14, and at the same time answer the following questions:

1. By "spring dwindling" do you mean the act of bees flying out too early and chilling, never to return again, or dying from old age without leaving the hive?
2. What is sorghum syrup?
3. By curing paralysis does O. O. Poppleton sprinkle the sulphur on the bees and combs dry, or does he mix it with water?
4. Where can I find any information in regard to queen cramps?

5. Under "bee paralysis" you say, "Destroy the queen of an affected colony." Now, does the germ of paralysis affect the blood or vital bacteria of the brood or not? If not, why destroy the queen? By what germ is the paralytic contagion spread (in what manner)? If the queen is destroyed, would you advise requeening from a new strain?

6. Please give a little more detail in general, and state the symptoms of chilled brood, overheated brood, poisoned brood, starved brood. In any of these three cases, will the bees remove the carcass of the larva or does this have to be done by the apiarist? In how many of the above cases does the brood die?

7. Does spraying poison ever kill adult bees?

8. Will the dead mass of American rofy foul brood invariably rope?

9. Will the color sometimes vary outside of the coffee-brown tints described?

10. Do the cells containing dead larvæ invariably sink as soon as life departs from the grub, or how long after? Does the capping fall first and then the grub die?

11. About how long after the disease affects the first portion of comb does the odor make itself noticed?

12. Is the rofy test a base symptom, or, so to speak, a *dead-sure sign* of American foul brood, or does *this symptom have to go hand in hand* with the others in order to prove the case?

13. How can you manage bees at night? I tried it once, and they stuck to every thing and could not be made to go in at the entrance after the hive was closed, clustering in front all night. Could not a tent be placed over the hive at night, and the manipulation carried through next morning?

14. By the McEvoy method are the bees left to go and come after they have been brushed for the first time on a starter? If so, why would not the robbers take the disease-tainted honey just stored from the sacks of the brushed colony and thus spread the contagion?

15. Page 138 of the last edition of the ABC and X Y Z of Bee Culture, what can you use honey for that has been extracted from foul-brood combs?

16. Page 138, why do you say, "As soon as brood hatches out of healthy combs extract the honey and melt combs" if the brood hatches? If the brood hatches out healthy, why melt the combs?

17. Page 138, has this ever been proven by experience? How can a colony be cured when the bees have intercourse with the diseased colony and the honey therein?

18. Page 140, is all the brood in the hives taken away and bees shaken on foundation after being dequeened, or do you mean, in other words, no egg-laying is allowed? Are the queens destroyed or put back again after the lapse of time?

Whitstone, L. I.

ADOLPH LOEHR.

[1. "Spring dwindling" is the term used to describe a number of evils. It may be caused by the bees flying out too early, as you say; by dysentery; by too great a mortality, due to too large a number of old bees in the hive in the spring, etc.]

2. Sorghum syrup is a syrup which is glucose in its nature, made from the sorghum, otherwise known as Chinese cane.

3. Mr. Poppleton sprinkles on the dry sulphur instead of mixing it with water and pouring it on.

4. It is not often that a queen has the cramps; but sometimes, if one is picked up that is in the height of laying, and heavy with eggs, and is handled somewhat carelessly, as by an amateur when clipping, for instance, she may turn over, stretch out, and appear to be dead. After a few minutes, however, she usually begins to move a little, and finally is able to walk again.

5. Unfortunately, far too little is known in regard to the disease known as paralysis. This disease is not well named, however, for there are no symptoms like paralysis in the human family. A number of the bees will exhibit a peculiar shaking or tremulous motion as they stagger from the hives. It seems to be a disease of the mature bees rather than of the brood, and it is well known that certain strains of bees are less likely to be diseased in this way than others, and that is why it is a good plan to requeen whenever a colony shows these symptoms. It is not known just what is the way in which the disease spreads—that is, whether it is of germ origin.

6. The symptoms of chilled, overheated, poisoned, or starved brood are almost identical, and even experts are often puzzled by simply examining the brood alone. If the history of the colony can be taken into consideration it is generally possible to decide which is to blame—whether chilling, overheating, poisoning, etc. In the spring, if the combs contain no honey and

there is dead brood, it is quite reasonable to suppose that the brood starved, although, of course, if very cold weather occurs during the early spring, and the bees have more brood than they can cover, it is likely that the trouble was due to chilling. Overheating is not very common, but does sometimes occur during the very hottest weather when there is no ventilation through a proper-sized entrance, and when the sun shines directly on the hive. Poisoned brood would not be likely to be found in one colony and not in others unless it were known that this one colony worked on blossoms that had been sprayed, while others did not. With the advice that is going out now from all the experiment stations, practically, there is less and less blossom-spraying being done; consequently, there are fewer reports every year of poisoned brood.

A strong colony will almost always remove larvæ that have died from any cause except those that have died from American foul brood, and, of course, this is such a sticky mass that they find it impossible unless the colony is very strong with a large force of young Italian bees. Brood is likely to die from any of the above causes.

7. The spraying-liquids of poisonous nature often kill adult bees. Cases are on record where almost whole apiaries have been destroyed. For instance, Metcalfe & Parks, of Mesilla Park, New Mexico, have lost very heavily in this way.

8. The roping is the characteristic symptom of American foul brood, and we do not believe that there are any cases of this disease where the dead larvæ do not rope at all—at least we never heard of such.

9. The color of the dead brood is not a distinctive symptom, for dead brood of any kind is likely to turn various shades of yellow, brown, black, etc. There is really not very much difference in the color of dead brood, no matter what may be the cause of the trouble. In the case of a rofy type of foul brood the color turns darker as the disease progresses.

10. The cappings sink after the larvæ die. The cappings of larvæ that have just died are perfectly normal in appearance.

11. The odor from American foul brood varies according to the case. In some instances it is hardly perceptible, while in others it is so strong as to be noticeable when one enters the apiary. It usually depends upon the length of time the disease has been running; but we think it may be quite noticeable in some cases where the disease has just started; while, in other cases, where it is more advanced it might not be as strong.

12. It may be pretty safely stated that if the ropiness of the dead brood is very pronounced the disease is almost sure to be American foul brood. However, there is likely to be a slight roping with the European foul brood, although usually not nearly to as great an extent.

13. Handling bees at night is not difficult if the light be placed a little above and back of the hive—that is, the side opposite from the one in front of the operator. There would be no advantage in using the tent the next morning.

14. There is not likely to be much honey stored that is diseased; for the amount in the honey-sacs of the bees, that might be diseased, is used in comb-building; therefore the bees may be allowed to come and go. Robbers would not be likely to rob from brushed or shaken bees. We have never known them to do so.

15. Honey that has been extracted from foul broody combs may be used on the table. It is not injurious to man. Probably the majority who have honey from foul-broody combs boil it thoroughly and then use it for feeding back. There are some, like Mr. France, who feel that boiled honey is dangerous. Disease has sometimes returned when boiled foul-broody honey was given back to bees.

16. There may be some disease in the combs described, even though much of the brood would be healthy; and since it is impossible to clean up a comb diseased with American foul brood, there is nothing to do but melt it up. It is better to err on the safe side.

17. In this case the bees should be brushed again on foundation, after the brood above has hatched and the upper diseased combs removed. You will notice that the directions given here are to treat as before described; that is, go through with the process again of shaking on to new foundation.

18. The brood does not need to be removed in the Alexander treatment, for that which is in the hive already is allowed to develop. You will probably prefer to read the Alexander treatment as it was originally given by Mr. Alexander, and so we refer you to Nov. 1st GLEANINGS, 1905. The queens in this case are usually destroyed; at least, different queens should be introduced and the best Italian stock used.—Ed.]

# OUR HOMES

By A. I. Root

In all thy ways acknowledge him, and he shall direct thy paths.—PROV. 3: 6.

It is now the 15th of March, and I have made my last hatch with my two incubators before going to my northern home. A good many inquiries are coming in regard to that "simplicity" incubator pictured and described in our issue for Dec. 1. By the way, perhaps I should mention that I have not only taxed my brains but I have done more praying (that the Lord would "direct my paths") in regard to this incubator, than any other thing for some time. While all along I have had glimpses of success, I have reason to fear it was unwise to describe it as I did while it was yet unproven. I did it a good deal as I have done all my life, to set other minds at work on the problems that are confronting me; and, judging from the correspondence, I have succeeded pretty well.

I have already mentioned getting one hatch, from a machine full of eggs, of about 70 per cent; but when a neighbor, Mr. G. M. Raub, a York State bee-keeper who has recently passed his 80th birthday, on his first trial with a new incubator secured over *eighty per cent* (and has every chicken alive now), I began to think I and my incubator are a "back number." I think friend Raub got the chicken fever by coming down to visit me. As he had no previous knowledge with incubators I advised a sitting hen; but hens were too slow, and he made a trip to Tampa and came home with a "Mandy Lee" machine (the one I advised him to get\*) almost before I knew it. I called to advise him; but the new moisture hygrometer, and, as it seemed to me, the complicated directions, were such that I feared he would never do any thing with it. He sold 12 of the chicks to a neighbor of his, and gave the rest (close on to 70) to a single sitting hen, just as I have been advising, and I think every chick is "alive and well." Full of enthusiasm he filled the machine again (I think before it cooled off), and did almost as well, and now he is running the *third* hatch. I have the credit of furnishing him the eggs, or at least the greater part of them.

There is a big moral right here, friends, for old people like Mr. Raub and myself. Is there any thing nicer and more fitting for elderly people who want to be busy about something than caring for chickens? Such a one can, with a clear conscience, ask God to "direct his paths" in devising and planning for this innocent and harmless rural industry. Friend Raub lost his good wife but a short time ago; and so he is alone in his neat little cottage, surrounded by a very pretty Florida garden. He has his bright new incubator close by his bedside, and I

can easily imagine it is a sort of company for him while he enjoys studying it and giving it the careful attention it requires.

Well, we have another neighbor, Mr. Daniel Abbott, who, with an old Prairie State incubator that had remained unused for several years, took 187 chicks from 214 eggs. I furnished the greater part of the eggs for this remarkable hatch also. Well, after I heard of this and saw the fine healthy chickens, I tackled my Cyphers incubator, and, by closely following *all* the directions, I secured almost an 80 per cent hatch, and every chick is now alive—yes, very *much* alive—as I see them out of the window from where I write; and this brings me to the point of my story to-day.

Five days after starting the seventy-egg Cyphers I gave the old Simplicity 60 eggs for one more trial. In order to make out the 60 of fresh-laid eggs I took three eggs from a hen that had been sitting on them just about 24 hours, and I put a pencil-mark ring around each one of the three eggs. By means of a new thermometer called the "Inovo," that I got of the Prairie State people, I kept the temperature of the *eggs themselves* much more accurate than ever before, and in just 19 days two bright strong chicks hopped out of two of the pencil-marked eggs so quickly I didn't even know they were pipped; and you will recall that the eggs are moved from every shelf to the lower one every eight hours. This shifting three times a day is all the "cooling" and turning the eggs get; and examination on the 18th day with my egg-tester showed nearly sixty eggs with a live active chick in every egg. I noticed then these two eggs were plainly in advance of the others. Well, heretofore I have practiced shifting the eggs from shelf to shelf until all were hatched; but as Cyphers and others plainly declare the eggs are not to be touched or moved at all after the 18th day, I decided *this* time to stop moving, even if each egg is warmed only from one side by "contact heat," as has been already explained. At this time there were eggs on four shelves (see p. 740, Dec. 1), 14 on each of the three lower ones, and 11 on the upper shelf. Now, this upper shelf is not as warm as the three lower ones, and it is the one I always use to place the chicks just out of the shell, so it was desirable to get these *eleven* eggs out of the way; and, therefore, I warmed up the Cyphers machine again just to take those eleven eggs. Now mark carefully. One reason for the eight-hour shifting is *because* this top shelf is colder, and the eleven eggs that happened to be on it that particular morning were exactly like (and, in fact, a part of) the whole 57 fertile eggs. Well, *on the 21st day all of the eleven but one had produced a fine chicken, and that one was partly hatched.* If every egg from that upper shelf had produced a good chick why should not all of the other shelves? I was almost ready to shout to the boys back in old Medina that my incubator had given a 100-per-cent hatch; but Mrs. Root held up her finger and said, "Counting chickens!"

\* At that time this was the only incubator I knew of for sale in Tampa; but since then the Cyphers people have also opened a house there. See advertisements of both, also Prairie State, in this issue.

This is a bad place to stop, I know; but I think I must digress a little right here. Cyphers and other incubator manufacturers are very emphatic in saying you must not open the incubator to help chicks out of the shell, etc. They say, "On the 18th day shut up all ventilators *tight*, and don't open the door until the hatch is over." Over against this advice the folks on the "baby-chick farms" open the machines any time to get chicks that are dry enough to fill orders, etc.; and Philo's "trick of the trade" is by *helping* chicks to break the shell, etc. Who is right?

This is what I did: I reasoned that, if Cyphers' machine was so much better after the 18th day, I would open the door and put *another* shellful in. I reasoned it could not hurt those already out and mostly dry, and the one almost out could stand it, and so I made the transfer. At this time, besides the two chicks on the 19th day, only about half a dozen were hatched in my incubator, and almost *at once*, so it seemed, every chick in both incubators "died in the shell."\* The one that was part way out stopped work when that door was opened; and, although the temperature was kept right up, and the door was open only a second or two, he never made any more progress until I removed the shell after the hatch was all over.\* Some of you may think all this a trivial matter, but in it I see two glimpses of God's wonderful laws and traces of his handiwork. First, what did that sitting hen *do* to those eggs during the 24 hours she had them that gave them the "send off" so they went through my clumsy machine and gave those two bright chicks so promptly?

The editor of one of the poultry-journals said it was of great importance that the temperature be pretty exact for the first week, but that it didn't matter so much about variations during the latter part. In connection with this it may be well to mention *again*, that, after a hen has been on eggs for about a week, they may be out of the nest as long as *three days and two nights*, at a temperature of 50 degrees or lower, and *still* give a good hatch of healthy chicks. Over and over again I find people throwing eggs away because the hen deserted them and they "got cold."

Well, my experiment, or, if you choose, *experience*, calls out two questions: First, if my 57 eggs had all been under a hen 24 hours (like the two) would I have had a good hatch?

Second, if I had shifted the whole 57 (instead of just the 11 on the top shelf) into the Cyphers machine, where there was plenty of room for all, would all or nearly all have hatched as did the 11? Even if I have not as yet had a really successful hatch with the "simplicity," have I not come pretty near

\*As the whole incubator cellar was close to 80, I don't think you can say I *chilled* the eggs by opening up, etc.

\*After it seemed likely no more eggs were going to hatch, I placed them all on a looking-glass, as I have explained, and only two "wobbled" to indicate life. These two I helped out of the shell, but will hardly make a "live" of it.

it? I am now satisfied a thermostat to control the temperature would be a decided advantage, for, in fact, just before I removed the 11 the heat went up one night so I feared all were injured; but as *these* hatched so finely I was forced to conclude none of them were harmed.

There is another beautiful text in line with the one at the head of my talk to-day. "But the path of the just is as the shining light that shineth more and more unto the perfect day."—Prov. 4:18. Now, suppose we change the word "just" to the words "honest, unselfish investigator" (and I think we have a right to do this), and see what a grand incentive we have to push on. My "pathway," both in bees and poultry, has been blessed all along by additional "light," pointing continually to the more "perfect day" ahead; and I will close by giving one more of my recent "discoveries." You will recall how many have decided that the fireless brooder needs a little heat for the first few days unless the weather is very warm. Well, after reading on page 166 how friend Clough kept full-grown hens in his lampless brooder to get eggs in winter it occurred to me a *sitting hen* could be put into this brooder for a week or ten days, and she would be cheaper and better than any lamp. Well, when I recently took 55 chicks from my Cyphers machine, I had a hen with eight half-blood Buttercups only a few days old. I raised the upper part of the brooder up to the highest notch, and, toward night, induced the hen to go in with her chicks with very little coaxing, and *then* induced the 55, just as they came out of the incubator, to run into the brooder about as you would run a swarm of bees into a hive. I made a little dooryard of netting around the brooder for the first few days, but now she goes everywhere with her "swarm" of chicks, and hasn't lost one. As they are close to the highway they are a delight to the eyes of passersby, old and young. Say, now—what's the matter with my "lampless brooder"?

---

#### HOW TO MAKE AN EGG-TESTER; AN EXPLORING EXPEDITION INSIDE OF AN EGG-SHELL.

I have visited Yellowstone Park, Mammoth Cave, Niagara Falls, and have enjoyed them all; but I am not sure but that the tracery of God's handiwork in an egg-shell during incubation has not given as much keen enjoyment as any or all the others. The only conditions are a good egg-tester and a place to use it. The card below has suggested my topic.

*Friend Root*:—I notice in your poultry articles you speak of an egg-tester of your own invention. As I am a new subscriber, and there are probably others, could you not give a description of it in the next issue of your poultry article? You have my sincere sympathy in your loss of chicks by "varmints." I have had the same experience; but steel traps and good cats have banished them from the place. I hope you will have better success with the next lot.

Loda, Ill., Feb. 4.

WM. RIDEOUT.

The invention is not mine, but belongs to Mr. R. R. Root, of the Root Incubator Co., Cleveland, Ohio. Get a cheap pasteboard

box about 6x8x3½ inches. Mine is a box that contained "toasted cornflakes," by the Quaker Oats Co. Remove the top, and with a sharp penknife cut the sides so it will fit close around your face. Make the right curve where it strikes your forehead, and then the opposite side where it goes around your nose. The idea is to make a little "dark room" around both your eyes. All the testers I see figured in the catalogs are for one eye only; but I find it a very great advantage to be able to look with both eyes as you do with a stereoscope. Now cut a hole in the opposite end or what is usually called the bottom of the box, a little larger than a good-sized egg. Cover this with a piece of black cloth, soft leather, or, perhaps, better still, a thin piece of soft black rubber. Fasten this fabric over the hole with tacks or glue, but so you have it tight and close. Now cut a hole in the center of this rubber, about as large as a common spectacle-glass, and your machine is done. If made carefully, every streak or ray of light should be cut off around the egg when held against the opening, and also when the box comes up around the eyes. If you use spectacles you want strong magnifying power to see clearly 6 or 7 inches from the eye. Now with this you can quickly test fertility, even out of doors, and fairly well on a cloudy day; but to see what is going on inside the egg every day you want a darkened room, with a single ray of sunlight coming in about the size of an egg. Stay in the room, as I have before explained, until your eye is accustomed to the darkness; and then when this single ray falls on the egg opposite your eye you are able to see not only the machinery of unfolding chick life, but you can also see the antics of the chick before he escapes the ivory walls of his prison house. A day or two before exclusion these "antics" will cause the egg to move slightly when placed on a smooth cut-glass mirror. This is what I have termed "animated eggs."

#### NOT ONLY AN EGG-TESTER, BUT A SEX-TESTER.

I presume many of you have seen accounts in the papers of a machine that would tell sex, etc. I have passed it by heretofore as too ridiculous to be considered by any intelligent reader; but it seems the fellow has had the cheek to carry his "toy" to one of the poultry shows; but a reader of GLEANINGS was too much for him. Read the following:

At the recent poultry show at Madison Square Garden, New York city, among the novelties there was a "sure thing" egg-tester, the invention of W. Gunnerson, of No. 20 Garden St., New Rochelle, N. Y. The inventor claimed that his device would not only tell an unfertile egg from a fertile one, but would also determine the sex. The device was a small pendulum which was held over the egg to be tested. If it swung around in a circle it indicated a cockerel; if back and forth in a straight line, a pullet; and if it remained stationary, an unfertile egg. I devised a plan to test the machine; and, accompanied by Frank Rodgers, of *Farm and Poultry Magazine*, brought an egg for Mr. G. to test. The device was placed over the egg and commenced to whirl around in a circle. Mr. G. pronounced it a very fertile egg, and, if placed in an incubator for 21 days, it would hatch out a cockerel, and he would bet \$100 on it. I then took the egg, and, in

the presence of about fifty people, broke the shell and stated that it was a hard-boiled egg, and showed it to the spectators. Mr. G. said he did not care—there was life in it any way. The joke of the boiled egg spread all over the Garden, and next morning Mr. G. was kept busy testing eggs which, on breaking, all proved to be boiled, and the management then took a hand in the game and ousted Mr. Gunnerson from the Garden. The price of this marvel was the small sum of \$2.50.  
Yonkers, N. Y. WALTER C. MORRIS.

#### ST. CLOUD, BURBANK, OCALA, ETC.

In view of the many inquiries that are still coming concerning the Florida land-advertising schemes, we have thought best to give place to the following from the *Rural New-Yorker* of March 10:

You stated the exact truth when you said the lands of the St. Cloud Veteran Colony, of Florida, were almost worthless and almost uninhabitable. These land schemes requiring money to be sent in advance, and the land allotted by the promoters, always prove disastrous. The promoters work for their own interest; and to send them money is little less than idocy. Any one seriously meditating such a course may well be watched by his friends and put under guardianship before he has a chance to consummate the deal. Though no mention is made of irrigation, drainage, and fertilization, these are very important items. An acre of land in Florida irrigated and fertilized for one year will cost the purchaser from \$300 to \$400 on an average. I have not seen an acre of land to be relied upon to produce a crop without from \$60 to \$80 worth of fertilizer, unless it be some of the muck land which does not require quite so much. If several crops are raised on the same ground, each one must have additional fertilization. And the market is very uncertain. I could tell you some distressing cases in connection with this colony. One man came all the way from Washington State only to find that the promoters had deceived him. M. C. L.  
St. Petersburg, Fla.

It seems too bad to have to give so much space to one scheme. We have referred to it often; but when schemers take advantage of the sentiments of old soldiers, and through pretended interest and comradeship, deceive them and rob them for personal gain, one feels justified in any honest effort to block the game. Do not send money to any land promoters anywhere. If you want to buy in any section, first investigate yourself or through trusted friends.

I am credibly informed that some of these "promoters" buy up blocks of land for, say, \$2.50 per acre, or even less, and then persuade their victims, they are getting a great bargain at all the way from \$10.00 to \$30.00 or \$40.00 per acre. Florida is a good place if you come, see what you are buying, and talk with people who have lived here for years.

#### THE "PROHIBITION LANDSLIDE" IN MISSOURI.

Mr. A. J. Root—You will be glad to learn that Jasper Co., Mo., went dry by a handsome majority (excepting the city of Joplin), in the recent fight against the saloons. As a result of this election (closing yesterday) 28 saloons must cease doing business as soon as their present licenses expire, which will vary from one to about six months. The prohibition people are not going to stop at this; no, we are going to have a dry State; then we shall get Joplin, a very wicked city of about 60,000 population and some 40 saloons.

Jasper County's greatest resources are the lead and zinc mines. These mines employ lots of men, and they are nearly all whisky men; therefore we are very much elated over the prohibition landslide that has swept over Jasper Co. despite vigorous efforts of active opposition.

Oronogo, Mo., Feb. 5.

HOWARD PETEFISH.

On page 97, Feb. 15, it is asked, "Does alsike or white clover cause bloating in cattle?" I think not unless left till it gets large before pasturing; neither will red clover. Cattle that are very hungry should not be turned on to such pasture more than about one hour the first time, and that after the dew is off. I was raised in Hardin Co., Ohio, and had some experience with the bloating of cattle. After they get used to it there will be no danger of bloating.

## EDITORIAL

By E. R. ROOT

### NEW DRESS OF TYPE.

THE reader will notice the new dress of type. Our big subscription list, entailing heavy runs on the type, wears our faces much faster than formerly. While a thousand dollars' worth of type would formerly give us some two or three years of service on our journal, the same investment will run now scarcely a year.

### FAKES AND FAKIRS.

THE bee-keeping industry does not seem to be cursed with a lot of fakirs as is the case with the poultry industry. The bee business has fewer and better journals, and of a character that will not accept fake advertisements. The time was, in the olden days, when there were advertised moth-traps, bee-balm for drawing swarms, worthless patent hives, certain controllable bee-hives, and the selling of patent-right territory. These have all disappeared; but as one looks over the poultry journals of to-day he sees the devices for testing eggs, testing the sex of eggs, and a lot more things of a like nature that are fakes of the worst kind. Pick up any of our bee journals and you will find only straight honest goods advertised.

### FOUL-BROOD LEGISLATION IN MASSACHUSETTS.

ON March 25 the House of Representatives of Massachusetts passed an act having to do with the suppression and control of contagious bee diseases, and the matter is now in the hands of the Senate. It would be well for all interested to write to their Senators at once, urging their favorable consideration of the bill.

The proposed bill provides for the appointment, by the State Board of Agriculture, of a competent person as inspector of apiaries, who may in turn appoint as many as three deputies to assist him. The inspector's duties include the preparation and distribution of literature, inspection of apiaries, etc. Sections 3 and 4 make it an offense to keep diseased colonies except by an order in writing from the inspector that such are held in quarantine. Section 9 pro-

vides for an expenditure of a sum not exceeding \$500 during the present fiscal year in carrying out the provisions of the act.

### NO FLOOD OF HONEY FROM SOUTHERN CALIFORNIA THIS YEAR.

THE following letter just received from J. W. George, who is in close touch with the situation, will explain.

From present indications California will not flood the country with honey this year. What earlier looked like a bumper crop in the coast counties looks very discouraging now. My bees are fully a month behind what they were a year ago; and our cold April winds have commenced to blow, and that will retard them a good deal.

There have been several carloads of bees shipped into the valley this winter; but with one exception our two-mile-limit rule has been observed, and it is more than likely that the man who has disregarded the custom will be sorry of his bargain before the summer is over. The man who is being crowded out and controls about 1400 colonies, and he will certainly keep up his end; besides, he has the sympathy of every bee-man in the valley.

There is another problem confronting us now. Black brood was quite prevalent in the San Joaquin Valley last season, almost wiping out some yards. But the supervisors of this county are awake to the interests of the valley, and at their meeting the first of this month they passed an ordinance compelling all bees to be inspected at Imperial Junction; and as that is the only way for them to get into the valley we stand a pretty good chance of keeping it out; however, it will be well for every one to be on the watch, and at the slightest indication of any thing wrong the inspector should be called in.

Practically all of our last year's crop is out of the way. I think a hundred cases is about all that is on hand at present.

Imperial, Cal., March 28.

J. W. GEORGE.

It is strange that the season seems to be late in that section of the country, while it is at least a month ahead in the Eastern States.

*Later.*—March 31st Mr. Mercer writes:

A few days ago we had 1½ inches of rain. This will help us some, but not enough to make any thing like a crop of honey.

Ventura, Cal., Mar. 31.

### BEE-KEEPING ON A LARGER SCALE; TEN-FRAME VS. EIGHT-FRAME HIVES; POWER EXTRACTING-OUTFITS.

THERE are many evidences from bee-supply houses that show that the tendencies now are toward ten-frame rather than eight-frame hives, and large four, six, and eight-frame extractors rather than two-frame machines. When the power-extractor outfits were first put out it was not thought that there would be much of a demand for them; but in the West, where bee-keeping is carried on in any kind of large scale, power outfits are more and more supplanting hand-power extracting.

The time was when the eight-frame Langstroth hives took the lead. While they still occupy a very prominent place in the supply houses, the ten-frame hives are gaining ground every day. From some experiments that we have been conducting at one of our outyards, the ten-frame outfits seem to be in the lead, not only in wintering, but for honey. Father Langstroth figured out very carefully this brood-nest; and while a cubical brood-nest is theoretically correct, perhaps the dimensions that he gave us are more nearly right from a practical standpoint.

The eight-frame Langstroth hive came into existence because it was supposed that the ten-frame was too large for the production of comb honey. Later experience shows that, if there is to be any reduction in the size of hive-bodies or brood-chambers it should be along *vertical* rather than lateral lines; hence we see a strong tendency growing more and more toward the ten-frame hives, shallower than Langstroth, otherwise the same dimensions, especially shallow extracting-supers.

As we have said before in these columns, where one runs for extracted, the ten-frame is much to be preferred; and even if he wishes to confine himself to the production of comb honey, it is doubtful if he would gain any thing by adopting the eight-frame width.

The tendency all along seems toward a standardization of supers, covers, and bottoms as well as hive-stands, for there is nothing more annoying than to have two widths of hives in a yard, or different yards, one with eight-frame and the other with ten-frame size. As the latter seems to show a little the advantage in the production of extracted honey, and is probably nowise inferior for the production of comb, it is not at all surprising that the whole bee-keeping public seems to be turning more and more toward the ten-frame width of hive.

#### THE REMARKABLY EARLY SPRING IN THE EASTERN STATES; EXCELLENT WINTERING AND SPRINGING OF THE BEES.

FORTUNATE indeed it was that bee-keepers in most of our Northern States have had and are having a very early spring. Settled warm weather came on in many localities along about the first of March—something that was very unusual. A year ago at Medina we did not have really good bee weather until along toward the first of May, and even after that the weather was cool and unfavorable.

After our very severe winter there probably would have been a good many losses throughout the country had there not been an early spring. As it was, the weather moderated in the nick of time, brood-rearing started, young bees hatched out to take the place of survivors dying off. It follows, therefore, that, even if unfavorable weather should come on, there would be a large force of young bees in most colonies of practically all the northern and eastern States, and

to a great extent in the western States. When we say "eastern" States we have in mind territory east of the Mississippi.

Speaking of the spring in general, we have been having an old-fashioned spring, and, we may say, an old-fashioned winter. It is the kind that we remember in our early childhood days, when it was cold all winter and then it merged suddenly into balmy spring. For the last twenty-five years we have been having what are called open winters, many days of which the bees could actually fly when wintered outdoors. This class of winter in our locality would continue on clear up into the first of May, it being neither winter nor spring. Brood-rearing would get started, then get a bad setback by sudden cold that would last a week or ten days. The past winter and spring has been a delightful contrast. We had our winter, with good stiff steady cold, and now we have been having our spring—beautiful balmy days when all nature seems to be giving up praises to God for his goodness.

While it was getting a little dry in some sections, heavy rains came on in the nick of time; the ground is soaked, and the clovers and all plant life seem to be showing up with unusual luxuriance. We never saw a spring when the prospects for fruit-bloom and clover were more favorable, and, according to our prophet, Virgil Weaver (see page 197, March 15), whose prophecy is based on a series of observations made for years back, this should be a *clover* year. He predicted over a year ago that last season would be a failure, and his prediction was almost literally fulfilled for the section of country he outlined.

#### THE STATEMENT OF A HIGH AUTHORITY IN FRUIT CULTURE ON SPRAYING.

"The American Apple-orchard" is the title of a book by F. A. Waugh, recently published by the Orange Judd Co., of New York. It contains over 200 pages of interesting and valuable matter. Whether one is interested in growing fruit or not, he will find this book very readable. If he is an apple-grower he can not afford not to have it. It reminds us of the time we used to read the Tim Bunker papers, years and years ago. While we were not at all interested in agriculture, yet Tim Bunker's writings were so entrancing that we followed his series of articles as we would follow a serial story.

Well, this F. A. Waugh is a writer a good deal after the same style. We mention his work here because of the author's high standing in fruit culture, and because he advises against spraying trees while in bloom. Those fruit-growers in the vicinity of our bee-keeping friends, who insist on spraying at the wrong time in spite of the advice of experiment stations, all over the United States, and up-to-date fruit-growers, should be shown a copy of this work. If they are so behind the times as to spray while the trees are in bloom they have a lot to learn, and it would be dollars and dollars in their pocket to purchase a copy of this work and

read it carefully. We are not sure but that bee-keepers can afford to buy it and loan it out to their fruit-growing neighbors. For the present, at least, we can not forbear copying a portion of chapter 11, entitled "The Insect Campaign." Under the head of "Codling Moth," the worm that so often turns one's stomach as he bites into an apparently sound apple, he says:

This is one of the best known and most widely distributed enemies of the apple. Newly settled districts have nearly always enjoyed a temporary immunity from this pest, but experience has shown that the moth can not long be kept out of any commercial apple-growing district. Apparently the ravages of the codling moth are more serious in central and southern latitudes, where two or three, or even as many as four, broods are hatched in a year. However, the campaign against this insect is an annual one, and has to be fought in practically all the commercial orchards in the country.

The principal preventive of damage is the spray-pump, using poison sprays. Paris green is largely used at the present time, but is being generally supplanted by lead arsenate. Thorough spraying at the right time with these insecticides will very greatly reduce the percentage of damage. Indeed, in many cases the work of the insect is practically eliminated. As in dealing with every other insect or fungous pest, thorough spraying at the proper time is highly essential. The proper time in this case is within one week to ten days after the falling of the blossoms. A longer delay can not be made with safety. After about 10 days the calyx, or blossom leaves of the young apple, close and the apple turns to a pendant position. Before this time the newly set fruit stands erect with the calyx lobes open. A poison spray properly distributed falls into this calyx cup and the poison lodges there. As many of the young larvæ enter the apple by eating in at this blossom end they secure with their first meal a taste of poison which usually prevents any further apple-eating on their part.

*Special attention should be called to the fact that apple-trees should not be sprayed while in blossom. Spraying at this time is not always totally without value, but in many instances it is not only unnecessary, but even highly dangerous to the crop. Under all circumstances it is very likely to poison the bees working on the apple-blossoms. This sort of damage is far-reaching in many cases; and as the bee is one of the fruit-grower's best friends we can not afford to murder whole swarms in this way.*

This early spraying, just after the blossoms fall, will not usually catch quite all the codling moth, even all the first brood. When the second or third brood hatches later in the year a still smaller percentage can be poisoned by the arsenical sprays. Nevertheless it pays to give additional sprayings for this purpose in case the second and third broods appear to be large.

Note the special paragraph in italics, which are ours.

The price of the book is \$1.00 postpaid. It can be obtained of the publishers, Orange Judd Co., of New York, or of us.

#### AUTOMOBILES FOR OUTYARD WORK.

QUITE a large number are asking when we are going to give that extended article on automobiles, especially the article describing the machine or machines that will be most suitable for bee-keepers' use.

We have been gathering data from a good many sources, and hope to have ere long an article by which one can make a wise selection of a machine. We have no agency, and no ax to grind, and therefore shall look up machines that have earned a reputation for reliability and economy of up-keep, as well as low first cost. For the benefit of some of our readers who can not wait, a preliminary statement should be made. In the

mean time the Brush, made by the Brush Runabout Co., of Detroit, costing \$485, we believe to be a thoroughly reliable little car. The Reos—one, two, and four cylinder—are all first-class. We have had one and two cylinder machines in operation for the last three or four years. Cost of maintenance of two-cylinder touring-car, capable of carrying five passengers, has been less than \$50.00 a year, taking into account adjustment, repairs, and tires. This, of course, did not include gasoline, which will be from 12 to 15 miles per gallon for this type of car. The runabout Reo and the Brush will average, probably, from 20 to 25 miles to the gallon; indeed, the Brush has been known to make even 30 miles on a single gallon. While these \$500 cars carry only two passengers, a little wagon-box can be extemporized on the back to carry light freight. The Ford is also an excellent machine for the money. The Brush, Ford, and the Reos are pneumatic-tired outfits.

For all kinds of roads, especially mud, slippery mud, bad sand, we do not know of any thing better than the ungainly looking high-wheeled automobiles, with solid-rubber tires. This type of machine is usually not as well designed or built as those having pneumatic tires; but the one made by the International Harvester Company, of Akron, Ohio, bears an excellent reputation. The particular advantage of high wheels and solid tires is that the cost of tires is a very small item. There are no repairs on the road, no punctures, and these high buggy-wheels will run in mud as well as any common horse-drawn buggy; will not skid nor slip, as we know from some practical demonstrations that we have seen. The pneumatic-tired machines, while they can be made to negotiate mud, are not primarily mud-going machines. Do not let any agent or dealer try to convince you that he has an air-tired auto that will go in mud as easily and with as little danger as a common buggy. The facts are, pneumatic-tired machines slip and skid badly in thin mud, and it is a little dangerous to drive them along roads slanting toward a ditch or an embankment. On the other hand, the self-propelled buggies will negotiate roads slightly muddy about as well as roads that are dry or dusty. For year in and year out we are convinced that, *if well built*, they are coming to stay. They are awkward-looking, to be sure, and are not in keeping with the general styles of the pneumatic-tired low-wheeled machines, nor are they as fast. Unfortunately, quite a number of high-wheeled machines are poorly built and worse designed. Look out for all such, unless you want to pay a big repair bill and keep tinkering on the road. As soon as we can learn what buggy-type machines are reliable we will give a list of them. In the mean time we are safe, we think, in recommending the machine made by the International Harvester Co., of Akron, O. It is made in a large factory that is turning them out by the thousands.

## Stray Straws

By DR. C. C. MILLER, Marengo, Ill.

TEXAS ought to be a better honey State than it is with all that bigness shown, page 224.

THE GERMAN bee-keepers' association (Imkerbund) now numbers 90,062 members. —*Leipz. Bztg.*, 30.

AS TO foul-broody bees swarming out when thrown on foundation, doesn't it make a difference which *kind* of foul brood?

DR. BRUENNICH says, although his queens stop laying by August 15, colonies come out strong in spring on account of the bees' *longevity*. He thinks that is ever so much better than a lot of bees reared late to use up pollen stores. —*Schwz. Bztg.*, 60.

IDEAL conditions for taking out bees this year. March 20, soft maples bloomed. At dusk, opened cellar wide. Next morning, 31°, bright and still. Partly shaded cellar window. Quietly set bees on stands, closing entrances to one square inch or less. By noon, 62° with all bees out. Flew gloriously; no mixing; no robbing.

FOUL BROOD utterly destroyed an apiary of 20 colonies. The hives were sold to surrounding bee-keepers, and in every case took the disease with them. —*Schwiz. Bztg.*, 144. [The same thing happens in this country, and only emphasizes the great importance of an effective State law that will stop work of this kind. A bee-keeper who is so ignorant or indifferent to the rights of others should be held in check by a law that will protect those who are posted or have regard for the rights of others. —ED.]

JOHN H. LOVELL, p. 213, from what you say I suppose I said something about bees and roses not quite on the square, but you don't give page, so I'm left to guess. Perhaps I insisted that bees get nectar from roses. If so, I beg pardon. I don't know that they do, but I do know that they tear the buds to pieces. You say they are "looking for nectar." Don't you think "the mental attributes of the honey-bee are far too high to permit" it to do all that digging when "looking for nectar" where there is none?

ERLE SARGENT, I'd like to answer your seven questions, page 236, but the "boss" doesn't like me to talk "territory." But he may allow me just to whisper to you that, your foundation being wrong, your whole fabric topples. You assume that the man who owns land owns the nectar on it. Not a bit. He can't sell it; can't prosecute any one for stealing it; so he doesn't own it. So there, now. [The discussion of the right to certain bee territory we thought best to close for the present at least. We are no nearer a solution to this much-mooted question than we were twenty-five years ago. If there were as much diversity of opinion

among our legislators as there has always been among bee-keepers themselves we could never get a law that would give exclusive territorial rights. There would have to be united action before our legislators, no matter how favorably disposed, would pass a law. —ED.]

I DON'T KNOW enough to know whether it is better to disinfect all foul-broody hives or none; but here's a question: If it's necessary to disinfect a hive, is that enough? If there is danger from a spore on the wall of a hive, is there not danger from one on the stand at the entrance? If so, is there not danger from one on the ground close to the entrance? or further out? Just how far from the entrance does danger end and safety begin? Here's what I suppose the situation here: For every spore left in a hive there are 100 or 1000 of them on the floor at the entrance, and they are still plentier on the ground, thinning off as the distance from the entrance increases; yet for rods the ground is covered with millions upon millions of spores. Is there *no* danger from any one of these if there is danger from one on the wall of the hive? [The entrances and even the alighting-boards should be disinfected just as much as the rest of the hive. Years ago, when we disinfected our hives by scorching, we held the hives with a pitchfork over a bonfire and allowed the flames to strike the alighting-boards at the entrances. A common gasoline torch will do this work very effectively. —ED.]

E. FRANKE made a dozen fertilizing boxes with double glass. He saw a number of queens each return two or three times with mating-signs. The queen was balled for an hour upon returning unless she returned without mating-signs. —*Deutsche Bzucht*. [This matter of balling queens just returning from a mating trip depends upon conditions. We have just been talking with Mr. Pritchard, who raised 3000 queens last year, and who had abundant opportunity to observe and investigate. Under normal conditions, he says, bees will not ball their queen when they come back to their hive, whether fertilized or not. Sometimes bees will follow after a queen and pull away the filament that hangs to the end of her body. This question was also referred to our Mr. Bain, and he says this balling business depends on conditions. If bees have been allowed to get into a *habit* of robbing they may ball a queen, whether fertilized or not, when she returns from her flight. If a queen, on the other hand, he says, goes beyond the proper mating age for any reason, and fails to meet the drone, the bees may become disgusted and kill her by balling. They, or at least Nature, seems to know that an old virgin will probably not meet a drone, and hence she had better be killed. This principle applies in the case of a colony with a clipped queen that has tried to swarm repeatedly, and on the third or fourth failure to go forth with the queen the bees will probably ball that queen, thinking it is high time to get another. —ED.]

## Siftings

By J. E. CRANE, Middlebury, Vt.

Bees appear to have wintered well in this section.

If handling bees on a float shows off to as good advantage as in the picture on page 13 it must pay well.

From W. Mares' experience it would seem that the heat has quite or nearly as much to do with non-granulation as the sun's rays—page 771.

It looks to me as though the steam-heated uncaping-knife is one of the great improvements of the year in the line of extracting honey.

Mr. Holtermann's observations as to the value of bees fertilizing buckwheat-blossoms, page 5, are well worth remembering, as it adds more evidence of the value of bees to rural industries.

Mr. Poulder's reference to paper bottles, on page 19, is of interest. Can Mr. Poulder tell us who manufactures them, east or west? I have had only the address of the owners of the patents who were apparently interested only in the sale of machinery and rights to manufacture. I believe they have a large future for the sale of honey as well as milk.

A good deal is written these days about foul brood. It has been putting in its deadly work for several years in the southwest corner of our Green Mountain State, and it has been recently reported in the northwest and northeast corners. At the annual convention of the Vermont Bee-keepers' Association steps were taken to secure a foul-brood law for this State that will rid us of this scourge before it becomes more general.

On p. 778 Mr. Byer gives interesting facts about the law in Canada in regard to spraying fruit-trees. A kind of spraying other than for fruit-trees came to my attention by some of the Massachusetts bee-keepers, where poisonous mixtures were used to destroy the gipsy and brown-tailed moths. They told me the bees in the vicinity of such spraying were very soon destroyed. Could not a law be enacted that would compel such persons to use carbolic acid or something that would be distasteful to the bees so they would go elsewhere for their water?

Mr. Foster is right in saying that "too much can not be expected of the straw-board case. Several of these came to Denver from a distance of several hundred miles without any marks to show what the contents were." The honey was broken

badly. This is as we should expect, and we have always marked such cases so as to show their contents, and tried to get others to do so. If the bee-keeper will not mark his paper cases so as to show whether they contain honey or lead he had better use the wooden cases with glass fronts; but it seems that it is not much protection in the West, for Mr. Foster says, page 6, that the railroads out that way have claims for breakage on a very large percentage of the local shipments of comb honey.

For a score of years bee-keepers' have sought to put comb honey up in small packages; but to make bees work in a small section was, as a rule, to make them fritter away their time and accomplish little, so that it has, so far as I know, never proved a success. On pages 765, 766, Dec. 15, a method is described that has already been proved a success, which the editor modestly describes as "cut comb honey." I believe it would have been perfectly proper to put the head lines in larger capitals. I may be a little enthusiastic; but after reading over this article carefully two or three times I could have thrown my hat twenty feet high, and shouted "Hurrah! hurrah!" Just to think of honey selling at retail for a dollar a pound! Isn't it looking up some? And then to think that the whole business is already so well "rooted" that no penny-wise and pound-foolish bee-keeper can kill it. A new industry? Yes, and one that is destined to exert a great influence in the use of honey in this country. I believe; for if the dining-cars and big restaurants use it, the smaller hotels and restaurants will soon follow suit, and want little services of comb honey at a lower price; and one person will tell another how fine it is, and thousands will see it used and learn to use it themselves who would not otherwise have ever thought of it. And John Jones, when he comes back from Chicago, will tell his wife what a delicious meal he had on the dining-car, of warm rolls, butter, and honey; and she will inquire of her grocer for comb honey, for some night she will want to surprise John with honey and warm rolls, you know, and so it goes. But, hold a little. We had better not all rush into the new industry; for if we do, while we may not kill it we may hinder its growth. It looks very much as though it were a better industry for the city than the country bee-keeper, and that more careful handling would be required after cutting up than it is likely to get when shipped some distance. Another thing, it would seem as though it should be used pretty soon after it is cut up, as the honey that drips from the comb would granulate and make a rather unattractive-looking service; or does the person who cuts up the comb let the small blocks stand on wire cloth a few hours till dry? [Yes, they are drained.—ED.] We would also do well to remember that there must be some waste from the edges of the comb, and other defects. A pound of honey occupies almost 22 cubic inches of space, or  $\frac{1}{4}$  lb.  $\frac{5}{8}$  inches.

## *Bee-keeping in the South-west*

By LOUIS SCHOLL, New Braunfels, Texas

The 1910 census will be an unfortunate one for the bee-keepers' showing. The editorial concerning it on p. 65 coincides with my mention of it, Dec. 15, exactly. As I had stated, Texas' showing will be about half an average crop census. While some States will fare better, others will be even worse off.

### A GOOSE FOR A GOOSE.

Hey, Dr. Miller, don't those section-honey facts I gave on page 39 seem to strike you? Perhaps they strike you too hard. Yes, since I read it over in print I found what I had done—struck the section-honey producer a little too hard. And you, trying to get even with me, page 68, call me a goose in a roundabout way. When are *you* going to try some bulk comb honey? No need of your sympathy for our being flooded out, even if you join the Coloradans in a change.

### OUR NEW QUEEN-REARING YARD.

Does it pay the honey-producer to rear his own queens? Some of our best apiarists claim it does not, while many others are raising their own queens. To get nearer the truth of the matter an extensive experiment will be made along this line in connection with our work this summer. For years we have purchased our queens, upon the advice of some of our best bee-men, but with more or less unsatisfactory results. Resting on the supposition that our efforts at rearing our own queens can give us no less satisfactory results, if not better ones, we are making the trial.

We believe we can rear our own queens cheaper than we can buy them from some one else; that we can have better queens as a result of our own selection and careful breeding than those generally obtained from the average "rushed-for-queens" queen-raiser; that we shall have better results with queens right from our queen-yard over those that have been subject to several days' rough usage in the mails, and that we can have our queens just when we want them, without waiting for delayed orders, which alone often amounts to severe losses.

With as many as 26 apiaries for honey production we have a splendid opportunity for making a selection of breeding queens from which to raise our new queens. For instance, in one of our apiaries a colony of pure Italians has been the record colony for three years in succession, with only a few others coming up to it, first one season and then another. Such an excellent colony is good enough for a queen-yard, and so we took it there. In this way all the best colonies from each of the various apiaries find

their way to the queen-rearing yard. It gives us the best possible from hundreds of good colonies concentrated at one place. This place is an ideal one for the rearing of good queens and perpetuating the good qualities of the cream of our apiaries. Is it not possible thus to obtain some good results?

Of course it takes time to do this work; but I certainly believe that such a branch or department should be kept in connection with any large well-regulated system of apiaries, just as well as other lines of business have their different departments. Then there should be a suitable person in charge of that department. If we count on the superior queens that should be obtained in this way, the money saved that would otherwise go to others for queens, and an increase in our honey crops that must surely result through careful selection and breeding, our efforts should not be wasted.

While we have, from years of selection, some stock as good as may be desired, we by no means expect to stop importing into our yards new blood from some of the leading queen-breeders from time to time, toward still further improving our strains. Together with this we shall always employ the best, latest, and up-to-date methods in queen-rearing, so that our experiments shall not lack in that respect at any time.

### A LACK OF SPRING FLOWERS.

In addition to sufficient stores left the bees in the fall for the heavy spring brood-rearing a vast number of native spring flowers have generally been a great aid. But, due to more or less periods of drouth in the fall, winter, and this spring, there are fewer of these flowers this year than we have had for many years.

In consequence of this our colonies that had more stores early in the spring than for a number of years have drawn on these so heavily that many are in need, and have to be given from the heavier ones; and unless our April mesquite flow yields soon it may become necessary to feed.

The ground is covered with bloom in a fair season during April, as shown by the illustration on page 258. This is our State flower, the blue lupine (*Lupinus subcarnosus*), or called "blue bonnet" or "buffalo clover" by many. It grows in great profusion over the entire ground, making it look like a solid blue carpet for miles around. This presents a beautiful sight, and the perfume fills the air, the bees scampering amid the bloom in great numbers.

While the honey yield does not seem to be very great, it aids wonderfully with that from other bloom in building up colonies rapidly just when needed. It yields great quantities of bright yellow, orange, and red colored pollen. This year, however, the ground, usually covered by the blue carpet of bloom, is absolutely bare in most places, with only a few scattering plants in favored spots.

## Conversations with Doolittle

At Borodino

### CERTAINTY IN QUEEN INTRODUCTION.

"I sent \$10.00 for a special breeding queen. Now, have you any certain way of safely introducing a queen which has come on a long journey by mail?"

"The formula for introduction which comes with the cage and queen will answer very well where a man is buying from 10 to 100 untested queens, as the loss which occurs in using it is generally not large enough to pay for the extra work made by the absolutely safe introduction plans; but I had rather spend half a day on a very valuable queen than to run the risk with the ordinary instructions coming with the queen.

If you are willing to have the breeder in a nucleus, which many feel is best, then make a cage out of very thin wood and wire cloth, or of tin and wire cloth, large enough to take two of your regular-sized frames, and at the same time small enough so it will go into the hive and take the place of two frames. This is quite easily done where bright tinned wire cloth is soldered on tin ends and bottom. To this cage should be fitted a bee-tight cover. With the cage, go to any colony which can spare them, and get two frames of ripe brood—so ripe that you can see many young bees gnawing their way out from the cells. Shake and brush every bee off these combs and hang them in your cage. Now, before a window in a light room, so if the queen should fly you can not lose her, open the mailing-cage and put her and the retinue of bees which came with her in the cage with the combs of emerging brood. Put on the cage cover, all secure, and hang this cage in any strong colony, letting it take the place of two frames, which, if they have brood in them, can be put where you took the two from which are in the cage. Now leave the cage for from three to five days, when, an hour or so before sunset, brush every bee off the outside and carry it to the hive where you wish the nucleus to stand, and hang it in this hive. Now carefully remove the cover and take out the frames of brood, placing them next one side of the hive, adjusting a dummy so it will make a little hive the size of the two combs. Fix the entrance at the opposite side of the hive from where the nucleus is, and put on the hive cover, allowing the few bees adhering to the cage to crawl out and go on the combs with the others at their leisure. In a week or so give this little colony another frame of ripe brood, and you will have a nice prosperous little colony from which you can secure larvæ for queen-rearing as often as you wish, unless you raise queens by the thousand."

"Why do you have the entrance on the opposite side of the hive from the nucleus?"

"So as to prevent robbing. In all my

years of experience with nuclei, I never knew of a single nucleus being robbed out when established in this way. And very often, where robbing has started on a nucleus having its entrance right in front of the combs it contains, I have stopped it by changing the entrance, so to speak, by showing the combs over to the opposite side and putting the dummy next to them. In this way the bees from the nucleus go and come from the same place they have always done, and easily learn to travel across the bottom of the hive to their combs, so they are not bewildered as they would be by changing the entrance instead of the combs. A robber bee does not like to travel over a long space where there is danger of being grabbed by sentinels strung all the way."

"The combs of ripe brood should have honey enough in them to keep the little colony in good heart while in the cage; and when put in the hive, if there is not enough to make them prosperous a frame of honey should be set in next to the *side* of the hive, not next to the dummy. By thus setting, we put the honey this much further away from robbers, for they must pass clear through the little colony to get it.

"If you wish to introduce a valuable queen to a full colony of bees, take their queen away early in the forenoon, or long enough before so the bees will miss her presence a little before sunset, at which time take all the frames of brood and honey from the hive, and put in a division-board feeder full of feed. This feed is preferable made of granulated sugar, but extracted honey will answer. Set this feeder away from one of the side walls of the hive about the space of two frames, and with a bent wire hang the shipping-cage containing the queen and her escorts so the cage will come two or three inches from the back side of the hive and midway between the feeder and the side opposite it. Or it is just as well to put two empty frames in this space between the feeder and the side of the hive, allowing the caged queen to hang between them, down two or three inches from the top-bars. Before putting in the caged queen, uncover the candy, as per the directions accompanying the cage; and when all is ready, cover the hive. Now shake and brush all the bees off their combs down in front of the entrance to their old home, into which they will at once run; and, if done near sunset, few will take wing during the commotion which will soon commence when they find out the changed condition. They will run over the hive for two or three hours; but before morning settle down to the conclusion that they can not find their old queen or combs, clustering about the cage and new queen. The combs of beeless brood may be given in an upper story to another colony to care for during the next two days, or until the queen is out, and has commenced to lay in the comb which will be built from the food in the feeder when their old combs should be given back to them after the feeder and two frames are removed.

## General Correspondence

### IS IT THAT NEW BEE DISEASE?

Something that Attacks Adult Bees in a Peculiar Way.

BY B. I. GILMAN.

I am in trouble, and very much in need of your advice. I have about 25 colonies of bees in two apiaries. These bees went into the winter in very fine condition. Every colony was very strong in *young* bees, with plenty of honey. A light honey-flow the last of September enabled the bees to store as many as three combs of honey to each hive. They had quite a lot of pollen, also. The bees wintered splendidly. I looked over the apiary in February, and all seemed strong; but I noticed that the honey gathered in September had not been capped. I could not see that they had used any of it. It was all granulated. I did not examine the sealed stores any more than to notice that they were using them up; about March 1st I noticed flies at the entrance of some stands. I examined at once, and found the bees dwindled to a handful. In some cases the bees were gone, leaving frames of honey. I examined every thing and found the honey granulated—no pollen. In colonies that appeared not to be affected I found them building up nicely—brood, but no pollen.

After our experience of last year of a pollen famine and starved brood, which we quickly corrected after reading an article in *GLEANINGS*, entitled "Pollen Famine," we commenced to feed equal parts of first-class cotton-seed meal and flour, which the bees took readily for about ten days, when natural pollen began to come in. The bees, however, continued to die, and in some cases they left brood in all stages (eggs to hatching brood). The bees have diarrhea or dysentery—the alighting-board shows it.

We have been reading Dr. Miller's article, Nov. 1, p. 664, "Diseases of Mature Bees;" also the article that follows, "Animal Parasites as a Cause of Bee Diseases." We are fearful that this disease may be *Nosema apis* in some form, although the voidings are bright yellow, coarse, and very copious. There does not seem to be any distension of body or bowels in dead bees. The frames of the affected colonies are not "messed up" at all, excepting where robbers have worked on the granulated honey; and even there, there is no sign of voidings. We find no dead bees around the hives nor in them, excepting in two or three hives where the bees seem to have starved to death from want of food—our neglect; and even in there, no sign of evacuations on the alighting-boards or inside the hive. The disease seems to have "let up" in one apiary where the loss was about 10 colonies in 150—a big loss for

Southwest Texas. But at the home apiary they are still dying, but not so bad, however; and many affected colonies are building up nicely. In no case have we found a queenless colony.

The strongest colony in the home apiary, and one of the very few that have not been affected with this dysentery, has a golden Italian queen. This looks as though the golden queen were more immune than black or hybrid.

I will add that there are no apiaries within six miles of us; that some apiaries near Uvalde and Batesville are having heavy losses, probably from the same cause.

Pearsall, Texas, March 25.

[We have compared all the symptoms of the disease mentioned by Dr. Miller and Friedman Greiner, on pages 664 and 665 of *GLEANINGS* for last year. There are several things that suggest that it might be *Nosema apis*; although the voidings reported by you are yellow, you will notice in the articles referred to it speaks of the contents of the middle bowel being white. We do not know whether, in the downward passage, the contents become yellow or not. As it is, we are referring this to Dr. E. F. Phillips, of the Bureau of Entomology, and suggest that you send him at once bees that have died from this peculiar disease, and also a slat of wood or something showing the character and color of the voidings.

We would suggest that the affected colonies be put into a quarantine yard where there are no other bees, for we judge it would be dangerous to leave these bees that are affected in a yard where there are perfectly normal bees.

We can hardly think that the trouble can be due to pollen famine. While the lack of nitrogenous food affects the development of brood, it does not in any wise have any effect, direct or indirect, on adult bees. The fact that you notice that the bees are dying off in such large numbers shows that it is a form of dysentery; but as we have had such mild weather, if it is the old-fashioned kind we would naturally expect its ravages to let up after the bees get to flying. We should be pleased to know whether any of our subscribers have seen any thing like it.—Ed.]

### SPRING FEEDING.

Stimulation Usually Detrimental Because of Cold Weather that is Likely to Follow.

BY LEON C. WHEELER.

The advent of spring brings up again the mooted question of spring feeding. A few years ago, before I had tried it extensively, I was an enthusiastic believer in stimulative spring feeding; but as I began to make use of it in a general way I soon made up my mind it is largely a question of locality whether it would be a success or failure, and that in my locality the latter was the case.

When it was apparently settled warm weather I introduced my feeders and began feeding warm syrup, about half a pint daily. In a short time I could see quite a perceptible increase in the brood-rearing, and each hive contained all the brood the bees could cover, and I patted myself on the back. Conditions around the hive seemed to be about the same as during a light honey-flow; and as I watched their rapid up-building my enthusiasm for the system waxed high.

But my enthusiasm was destined to be short-lived, for there soon came a miserable cold spell of weather; and the bees, attempting to cover all the brood, lost down to a smaller amount than they would have had had there been no stimulation. When the cold spell was over, the dead brood was all dragged out unceremoniously by the bees, and deposited in front of the hives. Somehow as I examined those piles of dead brood my hopes of a bountiful harvest, which had been running high, suddenly dropped to zero. My enthusiasm for the system of spring feeding gradually oozed out. I was not entirely discouraged, however, but went on with the feeding until the beginning of the honey-flow. This honey-flow found the bees in as poor condition to gather it as any season since I have been in the business.

I have since tried it to a limited extent on a few colonies, beginning late in the season; and, while I have never had quite as bad luck since, still I have never been able to see that the colonies so fed showed any perceptible gain over those given combs of sealed stores, if, indeed, they did as well. The last two or three years I have made a practice of saving a lot of combs filled with honey gathered from the late fall flowers. This honey is not fit to use for winter stores, neither is it of any account to extract for sale; but for spring feeding it is excellent. Much of it is gathered so late that the bees do not cap it over, and will, for this reason, make use of it much more readily when set in their hives in the spring. As soon as the weather will permit, all colonies are examined and supplied with these frames of honey, each colony being given sufficient to last it until the honey-flow. Since using this method I have never experienced any difficulty in getting my bees in prime condition for the flow. Even colonies appearing to be very weak when opened up in the spring will usually, if given plenty of stores, be ready for the flow when it comes. If a few colonies do not appear to be building up fast enough to be in condition at that time I begin about two weeks before the flow, exchanging hatching brood from some of the overstrong colonies for eggs and unsealed larvæ from the weak colonies. This brings them to the required standard, and also helps to prevent the larger colonies from getting too crowded before the season.

Many writers have made the claim that a frame or frames of sealed stores would act as a sort of division-board in the hive, and that brood-rearing would be carried up to them and stopped. Now, this has never been the

case with me; and, in fact, it very often happens that the best colonies I have are those which come out in the spring with a hive crammed full of sealed stores.

As I said at the beginning of this article, I believe that locality plays an important part in this discussion, and I can readily believe that, in a locality similar to that of the late E. W. Alexander, for instance, or in any other place where the main flow comes on after a long spell of settled weather, stimulative feeding can be carried on with profit to the apiarist.

But where one is liable to have cold raw spells of weather, and even snowstorms, sometimes right up to the beginning of the honey-flow, the system is worse than useless.

Barryton, Mich.

[Our correspondent's experience is quite in line with the experience of others who reported on this matter something over a year ago. The latest practice for most localities is to *feed liberally in the fall*; then in the spring, if certain colonies run short, to give combs of sealed stores that have been held in reserve, or from some colony or colonies that can spare them.—ED.]

#### A PLEA FOR THE RETAILER.

Co-operative Selling vs. Individual Selling of Honey.

BY T. EDWARD DIENER.

The article by Wesley Foster, p. 105, Feb. 15, indicates that the writer has had some unpleasant experiences with unwilling retailers, as he winds up by condemning the whole retail business as being responsible for the high prices of all articles designed for consumption. It will certainly take more than one man to solve the economic problems of the day, as they are not to be laid at the door of the retailer. I am not answering the above article because I feel capable of solving the problem, but because I wish to see the retailers of the country justified. I myself am a retailer, not of groceries, but of men's wearing apparel.

In my estimation, retailers have been hurt by the statement that they charge an excessive profit; but the fact is that, while the retailers are compelled to advance prices continually of late, their percentage of profit has been reduced. Of course, there may be occasional cases of profits of 38 per cent, but the average is considered to be about 25 per cent, out of which 10 per cent goes toward the payment of the running expenses of the business, such as light, rent, help, etc. But this does not cover many additional risks that occur in some lines, such as damaged, rotted, spoiled, faded, or out-of-style stock. This comes out of the other 15 per cent, so that the retailer is allowed, say, 5 per cent on his investment, and perhaps a few per cent for the time he gives to his business. There are many

lines of goods that are sold near the cost price, on which the retailer can not advance prices.

Mr. Foster thinks that co-operative selling might help the problem, but I do not believe so. Co-operation is effected for the purpose of getting as big a price as possible. We have good examples of what co-operation does in the large city department stores in a retail way. They do not sell any cheaper than individual retailers, on an average, but they do screw down the wages to a sinfully low standard, the surplus then going into their pockets as additional profits. If some individual retailers should get that amount of work out of their help they would willingly pay twice the wages paid by the department stores.

This economic problem will be solved in time by evolution, but all of us will have to work toward that end. In visiting farmers I occasionally find cases of waste in a variety of forms, which, if guarded against, would help to reduce the cost of some of the things from the ranks of the producers. We hear many encouraging words in the agricultural press of the good prices that all produce is bringing, which goes to show that the producers have also contributed their share toward advanced prices. I do not begrudge them this, for they certainly work hard enough to earn it.

Men not fit for the retail trade soon find out that it is best for them to retire (a natural law of business); but this hardly helps to increase prices, for competition keeps prices down to a central scale or level.

Elizabeth, N. J.

### BUCKWHEAT-GROWING.

**The Ground Must be Plowed Six Weeks Before Sowing, to Get the Best Results.**

BY PERCY ORTON.

J. H. McGowan's article, p. 151, on buckwheat-growing, interests me very much, as I am a New York buckwheat farmer. Plowing and preparing the land makes all the difference between a good and a poor crop. You who intend to raise any this year, paste this in your hat: Plow at least *six* or *eight* weeks before you intend to sow and harrow, or, better yet, *disk* with Clark's double-action disk harrow once each week. If the land was plowed the fall previous, so much the better. If you don't think this early plowing amounts to any thing, try early and late plowing in the same field, and see the difference. It will be one-third in favor of the early plowing. I raised 20 acres last season, which yielded 27 bushels per acre of silverhull. This makes the most and whitest flour per bushel—ours this year 27 to 30 lbs. per bushel, selling wholesale at \$3.00 per cwt.

I never sow as much per acre of seed as Mr. McGowan, and I don't wonder that he gets an enormous growth of straw when 1½ bushels of Japanese is sown to the acre.

With me that was always the variety that branched the most, had the greatest amount of false kernels, made the poorest flour, and the least honey. I have had no use for it on our farms for ten years. The old-fashioned buckwheat is superior to Japanese for flour and honey.

Mr. Alexander told me, three years ago next August, when I was there at his home, that the farmers in his locality did not produce as much grain or flour while raising Japanese as they did with the old-fashioned black or silverhull; that his bees would fly right over Japanese to get to the black or silverhull. I mentioned this on p. 1504, Dec. 15, 1908.

#### THE AMOUNT AND KIND OF FERTILIZER.

I want to say that my best yields came from plowing and harrowing the field six weeks previous to sowing, using per acre ½ bushel silverhull, 30 lbs. nitrate of soda, 100 lbs. commercial fertilizer containing phosphoric acid 8 lbs., and potash 8 lbs., together with one bushel of sifted wood ashes, all mixed together and sown with a drill. This field contained six acres, 4½ of which was plowed early, and the other 1½ acres plowed and fitted two days before sowing, which was done July 8, 1909, and gave a yield of 165 bushels. The 1½ acres plowed last did not average half as much as the rest of the field. One acre of this had been in potatoes the year before, and was heavily manured. I expected the largest yield on that one acre, but was mistaken, as the sod ground did the best. It is very hard work to reduce the crystallized nitrate of soda so as to have it pass through the drill; therefore I shall use a commercial fertilizer containing nitrogen, 3½ lbs., phosphoric acid 8 lbs., potash 8 lbs., in every 100-lb. sack; also one bushel of *sifted* ashes. Set the drill to run 200 lbs. of fertilizer to the acre.

One of the "old granny" whims is the time to sow buckwheat. I say, sow it any time after all danger of frost is over in the spring—here, any time from June 1 to July 1—the earlier the better. If you ever planted potatoes on an old buckwheat-field some seed from the old buckwheat will always come up, and such always have the plump-est grain, even if it started to grow in May; therefore I don't take stock in late-sown buckwheat to prevent its "blasting" in the hottest weather, even if older persons say so; for in this section we sometimes have killing frosts as early as Aug. 27. Look out and get in between frosts.

Northampton, N. Y., March 7.

[One of the best crops of buckwheat we ever had was sown in the spring as soon as frost was out of the ground.]

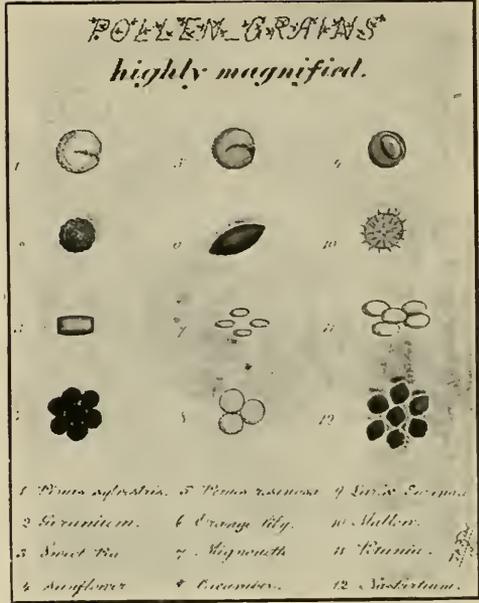

We are interested in that statement to the effect that Japanese buckwheat is inferior, both in point of honey and flour to the old-fashioned kinds. If we are not mistaken, we have had reports before to the effect that, although Japanese furnished more straw and more bushels of grain, it actually furnished less flour and less honey. How is this, friends?—Ed.]

THE AGENCY OF BEES IN FERTILIZING PLANTS BY MINGLING THE POLLEN.

BY E. R. ROOT.

[The following is a portion of a chapter on pollen, in the new edition of the A B C and X Y Z of Bee Culture, now in the press. As it shows the intimate relation between bees and flowers we reproduce it in these pages at this time so that our readers may see and verify some of the wonderful things in nature. It is important, too, that the bee-keeper be informed as to the intimate relation between his industry and that of fruit-growing. Some fruit-growers and farmers are so ignorant that they imagine their neighbors' bees are robbing their flowers. They are just the kind of chaps who spray when their trees are in full bloom. A knowledge of the facts, as well as a little diplomacy, is needed to get such men to see that, so far from killing the bees (the goose that lays the golden eggs), they should welcome them as their best friends. The facts are gleaned largely from Fletcher and Cheshire. The latter appears to have drawn to some extent from Darwin and Gray.—ED.]

Before we consider the wonderful little schemes of nature to bring about the work of cross-fertilization, it will be necessary to give a few of the common terms employed in botany to designate the different parts of the flower. In the accompanying illustration we have a case of what is known as the hermaphrodite flower, that is to say, a perfect flower that is capable of self-fertilization. In most of the specimens that we show, we shall present deviations from the perfect flower. In most flowers we have the male and female organs, the latter represented by what is known as the pistil at the top of which is a receptive surface called the stigma. Sometimes there is a tube connecting the stigma with the ovary. This is called the style. The male organs are designated by the name of anthers. These contain little granules of powder known as pollen. Around the male and female organs are what is known as the corolla, con-

—From Fletcher.

sisting of leaves of various colors, and outside of these is the calyx, usually green. The stem that supports the anther is called the filament. The nectaries are usually located at the base of the pistil or the bottom of the flower as at B. The main portion of the pistil called the ovary is what constitutes the embryo fruit. In order that this may develop, the pollen from A must be conveyed in some manner to the surface of the stigma as at C. The fertilizing fluid passes downward, causing the fruit to develop. It would be well to bear in mind these botanical terms in the description which follows in order to understand how beautiful and perfect is the design of nature in bringing about cross-pollination.

Something should be said regarding the evident intent of nature to bring about crossing between the species both in the animal and the vegetable kingdom. Among animals, inbreeding has a strong tendency to weaken offspring. The same principle holds true to a certain extent among plants. "A study of the devices provided by nature to insure cross-fertilization," says Dr. Fletcher, forms one of the most charming branches of the whole study of botany." The great naturalist Charles Darwin is recorded as saying that the general principle can be seen running through all branches of the animal and vegetable kingdom. Although some plants, he says, can be and are fertilized by their own pollen, it is always of greater benefit to their descendants if the flowers be fertilized by pollen from other flowers of the same kind growing upon other plants. Darwin summed up his observations with the statement that "Nature abhors perpetual self-fertilization."

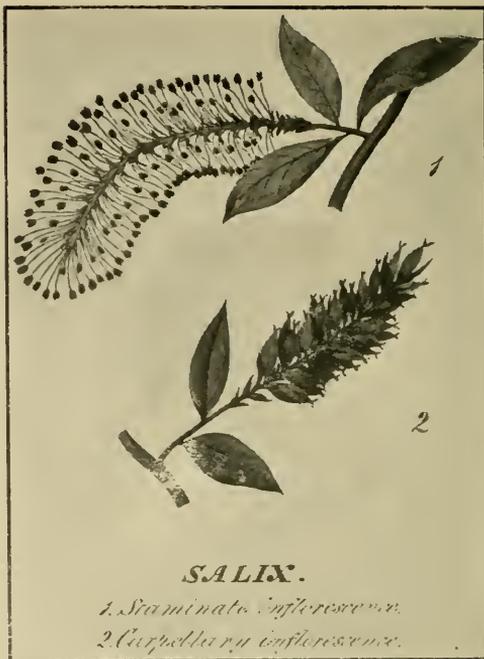

—From Fletcher.

Since then, says Dr. Fletcher, "endless observations have confirmed the accuracy of Darwin's law; and it has been found that in the vast majority of plants special appliances exist which will secure a more or less frequent inter-cross." And then he goes on to say that these appliances completely exclude the possibility of self-fecundation.

Coming now to the special agencies for the fertilization of plants, we may say in a general way that there are two, the animate and the inanimate. Among the first mentioned may be included wind, rain, and the force of gravity. There can be no question but that pollen from some plants is blown not only from flower to flower, but, in some cases, clear out to sea. Cases are on record where pollen from certain species of pines has been found hundreds and hundreds of miles floating in the air and lodging in the rigging of ships. Rain doubtless has a large influence, because it spatters the fertilizing element from one flower to another. Gravity must necessarily convey the pollen located on the tops of the trees or plants to the blossoms situated further down, whether on the same or other plant of the same species.

Among the animate agencies for the distribution of pollen, insects (and especially bees) are by far the most important. To a very limited extent animals and birds may assist. While insects other than bees undoubtedly perform a very valuable service, the honey-bee, from the very fact that it is out earlier in the spring than all other insects, must necessarily be regarded as by far the most important means of bringing about cross-pollination among our fruit-trees; and even when other insects are in the air, it outnumbers any other species, and possibly, in some cases, all other species combined, a thousand to one. Its general shape and size, the special construction of its tongue and its legs, all together make it especially adaptable for receiving and carrying pollen.

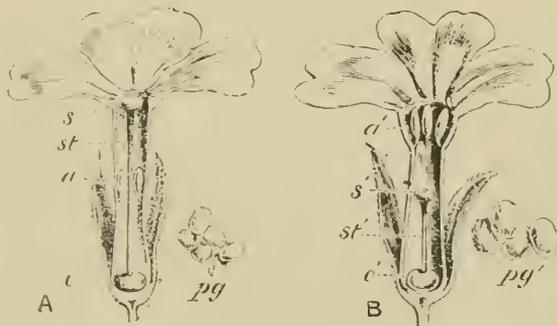

—From Fletcher.

In the willows, for example, the male catkins, that is, the portion of the flower bearing the stamens, appear on one tree while the pistils appear on another. This technically is called staminate and pistillate inflorescence. As the willows are a source of honey as well as pollen, and as they come to bloom very early in the season, it is apparent that bees must play a large part in their cross-pollination. Common cases of male and female flowers on the same plant are found in the butternut, hickory, birches, oaks, and hazels. In some instances the male portion of the flower comes to maturity before the female, and *vice versa*. In others there seems to be an effort on the part of nature, through a special form and arrangement of the parts of the flower, to prevent self-fertilization. In this case it appears that the bee, or some insect, must carry the pollen from one plant to the other.

Mr. Cheshire in his magnificent work, "Bees and Bee-keeping," Vol. I., gives a number of very interesting examples of the work performed by bees. While he appears to have drawn from Charles Darwin and Prof. A. A. Gray, his illustrations showing how Nature has sought to prevent self-pollination are so interesting and valuable, especially as they show the service performed by the bee, that we reproduce them here.

In Fig. 3 we have a cross-section of what is known as the common primrose (*Primula vulgaris*), that furnishes an example of

Cross-fertilization among some plants is brought about by the male and female organs, the stamens and pistils, being located in different flowers, sometimes on the same plant or tree, and again on separate trees.

one of the most remarkable cases of how Nature has schemed to bring about cross-fertilization. This is what is known as a dimorphic flower, that is to say, there are two forms of flowers on the same plant. At A the stigma of the female portion reaches up to the mouth of the flower-tube. The anthers, or male portion, appear about half way down the flower-tube as at *a*. At B we have just the reverse: the stigma stands about half way down the flower-tube while the anthers are clear at the top. The flower-tube itself is supposed to be about the depth of the reach of a bee's tongue. A bee comes to A, reaches down at the point *o* for its nectar. The anthers half up dust the tongue at a point about half way up its length. After the bee has secured its coveted sweet, it passes to the next flower, B, where the upper portion of the tongue and mouth becomes dusted with the pollen from the anthers, and the pollen dust that was secured from the other flower A will just reach the stigma in the flower B. The pollen dust that was received from the flower B will just reach the stigma in the flower A. There is another significant and interesting fact, that the pollen granules of B are too large to be received in the stigma of B, but

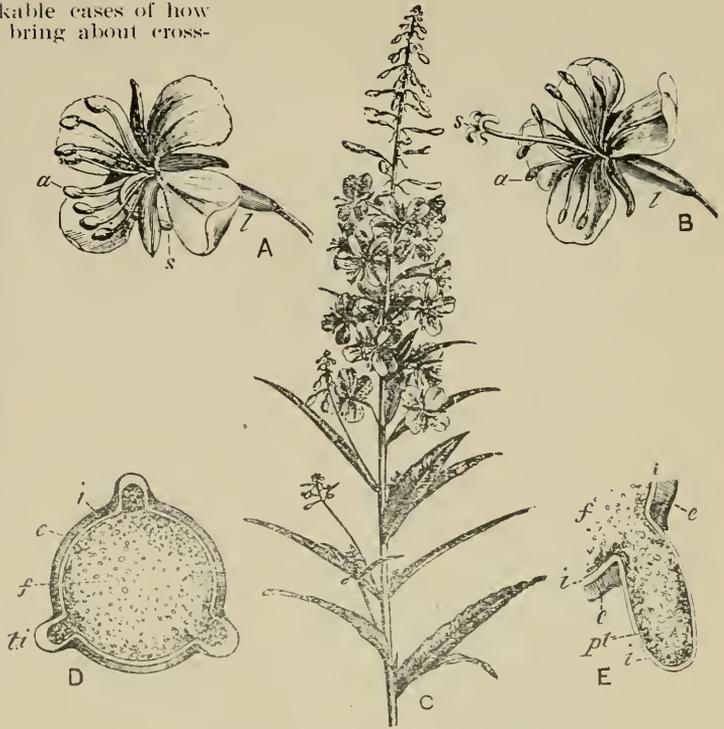

FIG. 4.—*EPILOBium ANGUSTIFOLIUM* (ROSEBAY WILLOW HERB), Order *Onagraceae*.—Gray.

just right to go in the stigma of A. Thus we see how nature has cunningly devised a scheme of what is called dimorphic cross-fertilization. In other words, she has so planned it that the pollen of the same flower can not fertilize its own stigma, hence we see the necessity of some insect of just about the right size, as the bee, of exactly the same tongue length that the bee has. Let us take another example.

In Fig. 4 we have a very pretty example of the fine honey-plant willow-herb; here the pollen of the anthers is sterile to the pistil or stigma of the same flower. At A, Fig. 4, we notice that the stigma, or the style, rather, as at *s*, is turned backward away from the anthers at *a*. At this stage the pollen at the anthers is ripe. A bee comes along, dusts itself over the pollen

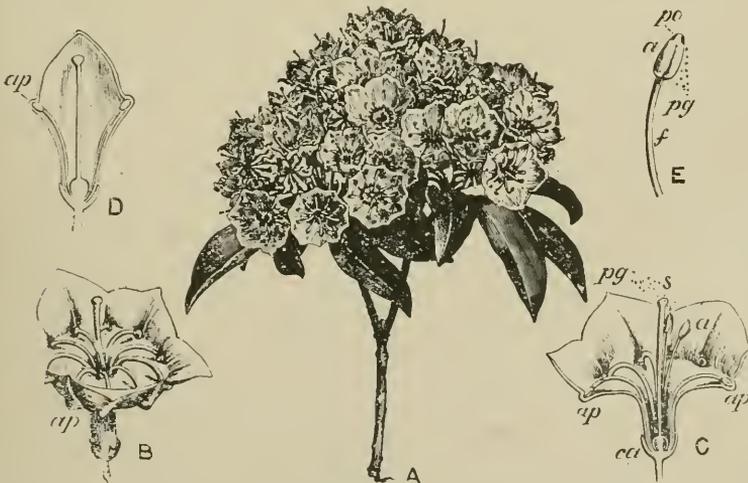

FIG. 5.—*KALMIA LATIFOLIA*, Order *Ericaceae*.—Cheshire.

in the act of securing nectar, and then passes over to B of a flower of the same species. Here the pollen is gone from the anthers, but the pistil has straightened out and the stigma is ripe to receive the pollen that the bee brings to it from the anthers of A of the other blossom of the same plant. It will be apparent in this particular case, unless insects, particularly the bee, carry the pollen from A to B, there will be no fertilization of the plant, and the bloom will die without fruit.

In Fig. 5 we have another case no less remarkable of a near relative of rhododendron and azaleas. The filaments bearing the anthers are curved downward, the anthers themselves appearing to be held in little pockets of the flower. Apparently they have no power of their own to release themselves. But a bee comes along, alights on the blossom, and as it

in cross-sectional drawing of B. The anthers and the stigma both touch the bee on the under side of the waist where there is a good deal of hair. The result is that pow-

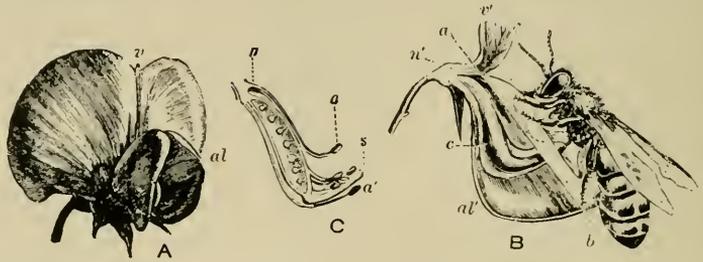

FIG. 6.—PAPILIONACEOUS BLOSSOMS, AND THEIR METHOD OF FERTILIZATION. —Cheshire.

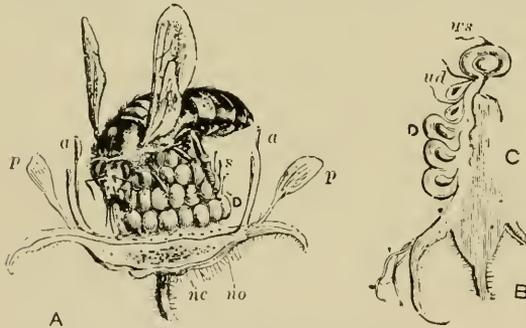

FIG. 7.—RASPBERRY (*RUBUS IDAEUS*, Order *Rosaceae*) BEING FERTILIZED, AND SECTION OF SAME. —Cheshire.

reaches around for the nectar jars these filaments loose, when they immediately fly upward, dusting the bees with pollen. This pollen now on the bee may fertilize the stigma or pistil of B; but as the bee goes from flower to flower the pollen is mixed, for each other insect visitation will continue on the process of cross-pollination. We have familiar cases of these anchored-down anthers in the rhododendrons, azaleas, and some of the swamp laurels. They are all honey-plants, but the honey is said to be poisonous.

In Fig. 6 we have a familiar blossom of the pea and bean, or technically known as papilionaceous flowers. At C we notice embryo bean or pea pod. At a we see the anthers and s the stigma. This whole thing is covered by a sort of wings. The bee comes along, pries them apart, and reaches for the nectar as shown

der is dusted on the waist of the bee; and as it goes from one flower to another, it mingles the pollen and dusts it over the stigma. The general shape of the flower is such that the wind could hardly accomplish much in the way of cross-fertilization, and apparently the bee has to exert some strength in forcing apart the wings of the corolla in order to get its coveted nectar.

In Fig. 7 we have the familiar raspberry blossom. This is a case of where there is very little color but considerable pollen and nectar to attract the bees. The anthers and pistils separated from each other appear in large numbers on each blossom. The bee alights on the head and reaches down for the nectar. As it does so, it brushes against the large number of anthers and pistils. In doing so it mingles the pollen, fertilizing the flower with its own pollen and with the pollen from other plants.

In Fig. 8 we have the familiar example of the apple-blossom. Note there are five stigmas and ten anthers. In many varieties of the apple, pear, and plum, the flowers are sterile to their own pollen; but, as Fletcher points out, they can be fecundated readily with pollen from flowers growing on another tree of the same species. We therefore see how very important it is to have insects, especially

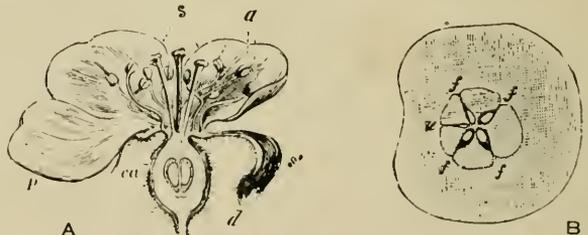

FIG. 8.—APPLE (*PYRUS MASUS*, Order *Rosaceae*) BLOSSOM, AND SECTION OF FRUIT. —Cheshire.

bees, to carry on this most important work of cross-pollination, without which there will be imperfect or no fruit at all. Many

tain sage, of California, we can realize the importance of this particular plant to the bee-keeper. Without this cross-fertilization the plant would undoubtedly "run out," as we say.

In Fig. 10 we have a still more remarkable case, as shown in the orchid. This flower is a little different in that the anther-sac has a sticky substance on the end, as shown at *r* in A. This pod adheres to the bee's forehead as shown at E and G. With this queer appendage containing its sac of pollen, the bee visits other blossoms, and, as seen at B, butts its head against the stigma and dusts it over with pollen. Chas. Darwin points out that this beautiful experiment can be accomplished with the point of a lead-pencil; but as it is not presumed that any foreign object should come in contact with the blossom except the insects we can see how insect cross-fertilization is accomplished in this most remarkable manner.

A REAL HONEY SIGN.

[The plan you describe, though good, is quite old. It is an old trick to most honey exhibitors. Our back volumes will show a number of engravings of raised and depressed letters in comb honey that have been shown at honey exhibits. It takes a good honey-flow and good bees to make a nice job. Not all bees will do nice work.—ED.]

### SIGNS MADE OF HONEY.

#### How to Teach Bees to Write.

BY HENRY W. BRITTON.

For a number of years I have been studying the bee, and it seemed to me that they could be educated to write, print, cut, and carve or engrave letters or characters upon the frames or sections of honey made by them so as to be used as a trademark.

With this idea in view I began trying to educate them; and after the first lesson given them, they spelled my name, *Britton*, backward, as you will see in the picture in the frame resting upon the hive; but after a few more lessons they spelled it all right as you can see by the frame I hold in my left hand.

This frame of honey is all capped over, having my name on it in raised letters.

These raised letters were made by the bees, and consist wholly of honey and wax. I have never seen any thing like this in any of the bee books or magazines, and believe it to be something new, and submit it to the readers of this magazine for their perusal.

At the Broekton, Mass., agricultural fair last year I received a special prize for this novel frame of honey, and also a premium for my observatory hive of "educated bees."

Stoughton, Mass.

### WATER REQUIRED BY BEES.

#### Some Interesting Experiments to Show the Exact Amount of Water Taken by Average Colonies in a Season.

BY B. J. WORSLEY.

From my experiments I have found that a good fair-sized colony of bees will take from 8 to 12 quarts of water during a season. I use watering-troughs made of concrete, similar in form to the Alexander feeder. I used five troughs, four of them for the bees and the other one screened so the bees could not get to it. The screened trough was for the purpose of determining the loss of water, during the period, by evaporation. There is a river about 20 rods from the apiary. The rainy days I had to disregard, as I had no control over them.

I once placed a new Alexander feeder under a good colony, in the month of May, put in it half a pint of clear water, and found that the bees took it in just two hours and twenty minutes. The greatest amount of water is used during the breeding season, for there is a large amount of water in the young brood.

I tried the experiment of placing frames of candied honey in an empty hive and con-

tracting the entrance to a small space. I put flour on the bees at the watering-trough and saw those same bees, marked by flour, go directly into the hive having the candied honey, stay inside from twenty to thirty minutes, then come out and go to their own hives. Later on they came out, went to the troughs for more water, then back to the hive having the candied honey. The bees kept on working this way until they very nearly cleaned up the combs in several empty hives that I placed for the purpose.

My bees are stationed about 20 rods from a mill-pond. The water in the pond is drawn down through the day, leaving the banks wet so the bees can get on them and pump up their supply of water. I found them so thick that it occurred to me that if it was water they wanted I could place it nearer, so the watering-trough was brought about. I am not certain how much they got elsewhere.

I believe there are locations where, in dry seasons, near-by watering would be a help. Since using the watering-trough I fancy that I have cut them off the pond by certainly a half.

Yes, bees certainly use much water and quite a little pollen. I like to have a corn-

field nicely filled out for fall breeding. While they store pollen, I think they run short in a dry time. How they lug it in after a rain! I put it down as a fact that bees use water and pollen in their business.

### SPRING CLEANING.

A Handy Device for Holding the Frames While they are Being Scraped.

BY SIDNEY S. STABLER.

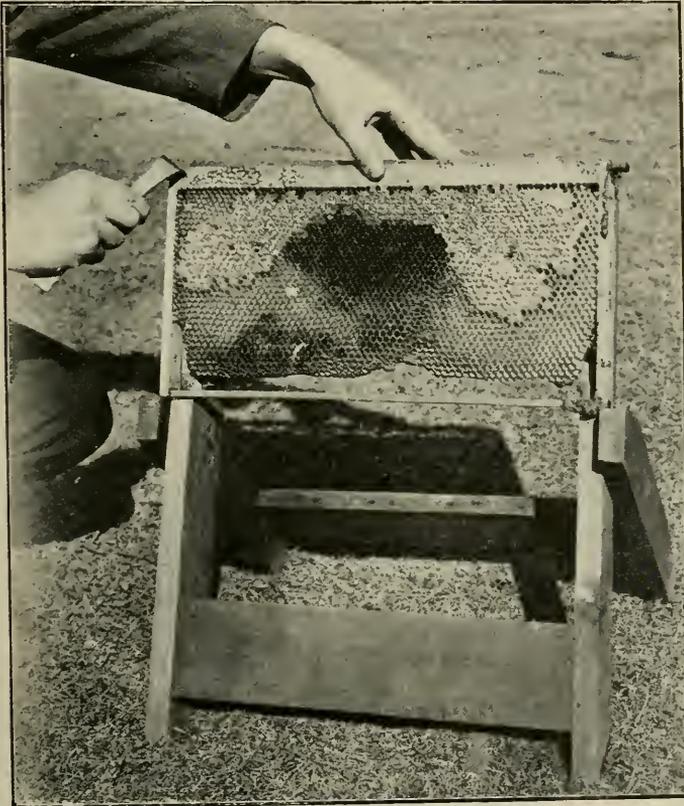

The accompanying photograph shows a device used at the apiary of the Maryland Agricultural College to hold frames in a firm position while scraping. It may be worth while for bee-keepers who make it their duty to scrape all brood-frames each spring to have one of these little "frame horses." They are just as a help in scraping frames as the "wood-horse" is in sawing wood, and perhaps more, because the wood does not mind jarring as the bees do.

The construction is so simple that almost any bee-keeper can make one in a short time. Perhaps the best lumber to use is  $\frac{1}{2}$  x 3-inch poplar or oak for the legs and braces, and just a thin strip of pine for the top-bar.

In using it I have a stool or box to sit on, and a hive-tool in my right hand and the horse in front of me. I sit at the back of the hive and take a comb from the hive and place it on the horse. I hold the top-bar with the left hand and scrape with the hive-tool in the right hand. Before I had this device I used to scrape over a box, but I like the horse much better. It will be noted that there is not much chance for bees to get mashed, as all the edges are purposely made sharp to prevent large points of contact.

With it we scraped all the frames from 20 colonies last spring, and intend to do the same this spring. We do not know how many bee-keepers make a practice of "spring cleaning" of frames; but we do know that too much of it can not be done, and that it can be much more easily done with some such device as this.

College Park, Md.

A SUPPORT FOR FRAMES THAT ARE BEING SCRAPED.  
*Photographed by Prof. A. B. Gahan.*

Carpet of "Texas State Flower," the blue lupine (*Lupinus subcarinosus*). The almost entire absence of this annual spring carpet this year indicates a dry season in most parts of the Lone Star State. See *Bee-keeping in the Southwest*.

[There ought to be some sort of tray under the frame-holder to catch the wax scrapings, otherwise some of them will get lost. Wax in any form always represents cash.—Ed.]

## TREATING FOUL BROOD IN A HONEY DEARTH.

Boiling Hives more Effective than Steaming.

BY P. C. CHADWICK.

In the East I never had foul brood; and when I met it face to face in this country I was somewhat nervous as to my ability to cope with it. However, as I was associated with Mr. J. K. Williamson my fears were soon over, he being a very careful observer. This article is largely due to his headwork.

In the spring of 1903 Mr. Williamson had his bees rented to two parties, one of whom, I am sorry to say, was not as careful with the disease as might be after having been warned of the possible existence of foul brood. The result was, in the spring of 1904 the disease had been spread by the interchanging of combs to such an extent that it was difficult to deal with it. The season was very dry, with no honey-flow; and with the usual tendency in such cases for bees to rob, it would have been absolutely ridiculous to have put these diseased colonies on foundation, as it would have meant starvation. We just watched them closely, and if any showed signs of being overcome by disease we melted the combs, scalded the hives,

and counted the colony lost save for the hive and wax.

Right here let me say that we have never had any trouble with hives used again after being properly scalded. Some of these colonies were carried over until the following spring with very little indications of trouble. Some we were compelled to melt up to save them from being robbed out, and the disease thus spread again. A few in which only a few cells appeared were "carved out"—that is, a small piece of comb was cut out around the diseased cells, and carefully destroyed; and, strange to say, most of the carved-out colonies are still intact, with no sign of the disease having reappeared after four years.

One colony, however, that was carried over during the dry year and put repeatedly on foundation the following season, and given nearly every known treatment for cure, during the following season was finally, as a last resort, sulphured at night, and bees, frames, brood, and honey were burned, after which the hive was scalded and used again. The wax from this colony might have been saved; but so many failures make one desperate, and thus it ended.

I do not believe Mr. Scholl's way of disinfecting, page 77, Feb. 1, is equal to thorough scalding, as this method does not reach the cracks and crevices as thoroughly as scalding water; neither do I see the object in scalding frames with lye and corrosive sublimate when hot water is just as effective, in my mind, and cleaner; besides, one can then save the adhering wax.

Redlands, Cal.

## CHEMICAL COMPOSITION OF HAWAIIAN HONEYS.

BY W. P. KELLY.

For many years the chemical composition of most products of commerce has, in a general way, been known. In the manufacture of some of these the entire process is subject to the strictest control, and the finished product made to conform very closely to a given analysis. Included in the list of substances coming thus under chemical control may be mentioned various food substances, although their chemical composition formerly received only a general study. In recent years, however, the chemical composition of foods has been more thoroughly investigated. It is a strange fact that while, for many years, certain articles of commerce received the attention of expert analysts, a large percentage of the substances that go to form human food were not so carefully investigated. The farmer, for instance, is much concerned about the composition of the fertilizers which he applies to his fields, and often quite exacting in his demands; but the articles of food that he purchases are consumed with little inquiry as to their makeup. The average American has not taken the trouble to inquire into this question, and in this connection it may be stated that, at least until recently, we as a nation were far behind the more progressive European countries in regard to this point. A general awakening of the public conscience to a more intelligent inquiry concerning the purity of the substances of food, however, has led to a more diligent and careful study of their chemistry. Our Bureau of Chemistry of the Department of Agriculture, led by the efficient direction of Dr. H. W. Wiley, has devoted no small part of its attention to this subject, and, as a result, the American consumer is becoming better acquainted with the composition of his food stuffs.

Among the food products that have received such attention may be mentioned honey, although its composition has, in a general way, been known for many years. In bulletin No. 110, of the Bureau of Chemistry, is shown the chemical composition of honeys derived from a wide range of sources; likewise the subject of Hawaiian honeys was recently set forth in Bulletin No. 17 of the Hawaii Experiment Station. From these and other investigations it is evident that the source from which honey is derived determines in a considerable measure its chemical composition. The differences between the composition of nectar honey, such as white-clover honey, alfalfa honey, and algaroba honey, are slight, being principally those of color, aroma, and flavor; but the composition of honey-dew honey is strikingly different.

There are small variations in the composition of the same type of honey, as is shown by analyses of samples drawn from different places. This is due, in the main, to the fact that the honey-bee does not confine it-

self wholly to any one source of nectar, and, therefore, the average honey is a blend of various nectars, and also usually contains some honey-dew. As an average of many analyses, however, white-clover honey has been found to contain the following percentage composition: Moisture, 17.60 per cent; reducing sugar, 71.75 per cent; sucrose, 1.75 per cent; ash, .07 per cent; dextrine, .80 per cent; and free acid, .06 per cent.

Honey derived from the nectar of alfalfa contains 16.50 per cent moisture; 73.60 per cent reducing sugar; 4.4 per cent sucrose; .07 per cent ash; .34 per cent dextrine, and .08 per cent free acid. The famous algaroba honey, which is produced in such abundance in Hawaii, has been found to contain 17.1 per cent moisture; 80.3 per cent reducing sugar; 2 per cent sucrose; .41 per cent ash; 3.57 per cent dextrine, and .1 per cent of free acid. The above analyses are for nectar honeys. We will now consider the honey-dew type, which is produced so extensively in Hawaii. This has been found to contain about 15.5 per cent moisture; 62.1 per cent reducing sugar; 5.25 per cent sucrose; 1.3 per cent ash; 10 per cent dextrine, and .15 per cent free acid. From the comparison of the above figures, it is apparent that honey-dew honey is quite unlike nectar honeys in chemical composition, containing considerably less reducing sugar, and very much more ash, dextrine, and sucrose.

There are, however, still greater differences between nectar honeys and honey-dew honeys than are shown by the above analyses. When polarized light passes through a solution of nectar honey at a temperature of 20 degrees it is usually rotated to the left, while honey-dew honey rotates the plane of polarized light to the right. After nectar honey undergoes "inversion," as it is called in chemistry, rays of polarized light passing through its solution are again rotated to the left at a temperature of 20 degrees; while honey-dew honey, on the other hand, continues to rotate to the right after inversion. Right-handed polarization in honey has long been regarded as evidence of adulteration with commercial glucose or sucrose; but in the case of honey-dew honey this explanation will not hold for its right-hand polarization, since samples of known origin, and those free from adulteration, possess this characteristic quality. Its explanation is found in the high percentage of dextrine and other gummy-like bodies which are always found in honey-dew honey.

Notwithstanding the material difference in chemical composition between honey-dew honey and nectar honey, both are natural products, collected and stored by the honey-bee, and as such are free from adulteration in the usual sense of the word, and may, therefore, be used without fear of their containing commercial glucose or other added sugars.

Algaroba is the source of one of the most beautiful honeys on the market. It is almost white in color, and possesses a very delightful flavor and aroma; and, although it is but

little used for table purposes, since practically all Hawaiian honey is sold to the baking trade, it has but few equals and no superiors as a table honey. Honey-dew honey, on the other hand, is a dark viscid substance, and is wholly unlike other honeys in flavor, etc. It is entirely used in the baking and confectionery trade, where it is highly prized, since it possesses baking and boiling qualities superior to that of other honeys. By far the greater part of Hawaiian honey is neither algaroba nor honey-dew honey, but is a natural blend of the two. In fact, there is no distinct division between the two types, each merging imperceptibly into the other. It has been recently decided by the Pure-food Board that honey-dew honey may be sold under the pure-food and drug act by being labeled "honey-dew honey;" and since it possesses such exceptional baking qualities, and is not brought in competition with table honeys, in so far as table use is concerned, it is quite certain that the demand for the product will continue to increase, and especially since it is now a well-established fact that honey-dew honey does not contain commercial glucose or other added sugars.

#### WINTERING ON HONEY-DEW IN A MILD CLIMATE.

##### Interesting Comparison of Vigor in Different Strains of Queens.

BY F. DUNDAS TODD.

The season of 1909 on Vancouver Island resulted in a complete failure so far as honey was concerned; but the bees did the best they could by storing up great quantities of honey-dew. It is needless to say I looked forward with considerable anxiety to the wintering, hoping the season would be one of the old-fashioned kind they talk about here when bees were confined to the hive for only a few days at a time. Pollen carried in on Christmas day, flights in the middle of January—these sounded good to me; but would they materialize in the day of need?

My duty, however, was to see that a reasonable amount of good stores was provided; so in the middle of September each hive was carefully overhauled, and an estimate was made of the stores, weak colonies being combined with three exceptions which I left as they were, to see what would happen. I have no desire to be a paragon of wisdom all at once, because you know a little foolishness provides a certain amount of excitement. Right here let me say two out of the three died, the survivor being the weakest of the lot.

Having learned the total quantity of stores on hand, the next step was to average by exchange of combs the quantity in each hive. The result was that about 17 lbs. of honey-dew was bunched in the center of the division (I use the divisible hive); then about 10 lbs. of sugar syrup was given to fill up the outside frames. Each hive thus had

from 27 to 30 lbs. of stores; but one was left with 40 lbs. of honey-dew and 10 lbs. of sugar stores to see what would happen. It turned up queenless in March.

Most of my bee-keeping friends did not feed until a month later. Probably they were wiser than I because it made more certain the consumption of honey-dew before winter set in. Given the same conditions again, I feel I would postpone feeding till the last possible moment.

The winter was not an open one by any means. Flight ceased by the end of November, and not a bee was seen until January 11, when sunshine and a temperature of 45° drew bees from most hives, some quite freely. Ten days later the weather was warm enough for a good flight; and as every hive showed signs of life the worst was thought to be over. Hives were hefted, and four that seemed light were given candy under the quilt. Out of curiosity the frames of one hive were quickly gone through, and note made of a patch of eggs covering a space three inches in diameter in one of the frames. On March 12 this same colony showed brood in four frames, but very little of it sealed. The overhaul of the apiary at that date indicated that egg-laying did not start until March 2, the day on which the first pollen was carried in.

On Feb. 8 one hive was suspiciously silent, and examination showed it to be dead of starvation, but with three frames of stores in the house—unfortunately, on the wrong side of the hive. Two weeks later the thermometer dropped to 18, and we got six inches of snow; but the thaw came on the 26th, with a temperature of 50°, and we had bees flying freely with snow on the ground. Four silent hives were opened, all being apparently dead, two hopelessly so. Two, being free of mold, suggested a possibility of a resurrection, so they were at once set over strong hives with wire netting between. Sugar syrup was trickled between the frames. Two days later one was alive, and therefore returned to its own stand; but the other was beyond hope of recall. This is the second time I have restored to life an apparently dead colony after a short cold spell.

Heavy rains followed the thaw. March 2 was warm and pleasant, so the bees flew freely, three colonies making a start with the carrying-in of pollen, the very first being the one headed by the best queen of last season's importation. It was in fine condition, having wintered with the loss of not over a hundred bees, as shown by an examination of the bottom-board on Feb. 15. About March 7 the weather was delightful, so the bees hustled in pollen at a great rate; and now was the time to make some estimate of inside conditions by outside signs. Several hives had plenty of bees flying about the entrance, but little or no pollen was being carried in; so, feeling suspicious, I overhauled the whole lot on the 12th, when the thermometer rose to 63°. In 21 colonies I found brood-raising was well under way; but 7 had no signs of eggs and no fresh pol-

len in the cells—in this respect being in great contrast to the colonies where brood-raising had been started, for there the golden-yellow pollen was conspicuous in areas as large as one's palm. Two days later the suspicious hives were gone through carefully; but no brood being found or queens visible, the colonies were combined with others.

By the middle of March the net result of my first experience in wintering with honey-dew in the hives was thus: Alive, 21; dead of starvation, 6; queenless, 8. The resurrected hive had, on Feb. 26, been combined with another whose queen was found lying outside. The combined colony showed brood in a couple of frames on March 12, but I noticed a slight dent in the abdomen of the queen.

Once the returns are in, comes the interesting work of making percentages of the results; but, unfortunately, it is not always easy to unravel the complications that naturally arise. For instance, I have bees in three styles of hives—eight-frame Langstroth, two division divisible, and one division divisible. Then I have at least three strains of bees, one being the old stock I bought here; another I got from Kentucky in 1908; the third from Texas in 1909. All in all, the stores were fairly uniform, as were the entrances.

I could not wait patiently for the final returns, but began to estimate from the number of dead bees on the bottom-board when I changed them on Feb. 15. One showed less than 100, while in others the corpses would have filled easily a pint measure—I am tempted to say a quart. I roughly grouped the hives into two classes of few and many dead, then proceeded to work out the results. First grouping by hives, I found that fifty per cent of the Langstroth fell under the heading of "many dead;" double division showed 16 per cent; single division, 6 per cent. Let it be noted here that, out of six Langstroth hives, five contained the old strain of bees. This is important, as later facts will show. On classifying by strains of bees I found 30 per cent of the old stock, 12 per cent of the Kentucky, and 16 per cent of the Texas had "many dead" recorded against them.

When the returns were complete I considered the death of the queen as equivalent to the death of the colony. Percentaging by hives first, I found one out of six Langstroths had died, equal to 16 per cent loss; three out of seven double-division colonies were lost, being 43 per cent; ten out of twenty-two single-division colonies died, being 45 per cent loss.

Turning next to strains of bees, I found half of eighteen old-stock colonies had become extinct; loss, 50 per cent; three out of eleven Kentucky stock; that is, 27 per cent; two out of eight Texas stock, being 25 per cent.

I have already reported in GLEANINGS great mortality among queens in this locality, hazarding the opinion that it was due to the lack of vigor in the stock, which, ow-

ing to the isolation on an island, had probably become decidedly inbred, and the above figures would seem to confirm my previous suspicions. This summer will probably see the end of this strain in my apiary. However, it is but fair to say that all the old-stock queens in Langstroth hives, five in number, survived the winter, and were showing good results in egg-laying by the middle of March.

A year ago I was of the opinion that one hive was as good as another for wintering in; but this winter the Langstroth is easily first. So I have still one more guess coming; also a second, for a few days ago I cursorily examined a few colonies belonging to a man who had left the province at the beginning of winter. I found them in homemade hives of not more than a foot in cubic dimensions, with entrances galore, several in the bottom just a bee-space deep, an inch and a half long, and at least one in each front about four inches from the top, this being circular, of  $\frac{3}{4}$ -inch diameter. As the bees were piling in pollen as busily as my best hives, I considered the colonies in good condition.

One hive had no quilt of any description, being merely covered by a plain board with cleats on two ends, so all winter it must have had more than enough ventilation not only through the upper entrance but through the top of the frames. Rain, wind, and frost had done their worst; but the bees were as spry as could be. The owner goes off for months at a time, and I could venture the guess he did not feed them in the fall, and, if not, they must have wintered on honey-dew. Such propositions make one ask, "What do we know about bees, any way?"

Victoria, B. C.

## REAR VENTILATION AT THE BOTTOM OF THE HIVE.

### How it Stopped Swarming.

BY S. F. PETERS.

I was much interested in the article "Ventilation of Hives during Summer," by J. P. Blunk, page 229, April 15, 1909. I had two colonies in Langstroth hives—one a new May swarm, and one from the year before. As soon as the weather grew warm I noticed a large number of bees kept from work by fanning, or ventilating hives by fanning; so I tried Mr. Blunk's plan by putting a  $\frac{3}{4}$ -inch strip under each side of the hive, leaving a  $\frac{3}{4}$ -front opening and a  $\frac{3}{4}$  entrance in the rear, full width of hive. Having only two colonies near the house I cut a strip of the proper length and height to slip into the rear entrance for cool days and nights. By reversing I could have a  $\frac{3}{8} \times 4$ -inch or  $\frac{3}{8}$  entrance, width of hive front. I watched my hives closely, and had entrances according to weather.

As soon as I made the double entrance all fanning was stopped, and bees went to other work. Sometimes the weather would get

warm while I was away from home, and I would find plenty of bees ventilating; but inside of ten minutes after the entrances were opened the full extent, all fanning stopped, and the bottom-board would contain only bees on the move, in or out of the hive.

When these colonies got strong enough to cluster outside (of only half a pint or so), I added another super to give them plenty of room. I put two rousing colonies into winter quarters. I had, of course, plenty of sections that were unfinished.

Another thing, while all my neighbors had swarmed after swarm from the same old hives, neither of mine swarmed at all. This would not have been unexpected from the May swarm; but the other, an old colony, failed to swarm, although it was a good strong colony. When the buckwheat flow was over I had three supers on each hive.

Brick Church, Pa., Feb. 2.

[If more of our bee-keeping friends would give more attention to bottom ventilation there would be less clustering-out and less of swarming. Our neighbor, Vernon Burt, thinks hives set up on four blocks off the bottom goes a long way toward stopping swarming altogether. It is such a simple trick it is a wonder that more do not try it. —ED.]

## CALIFORNIA STATE CONVENTION.

BY MRS. H. G. ACKLIN.

The twentieth annual convention of the California State Bee-keepers' Association was held in the Chamber of Commerce, the 14th, 15th, and 16th of February.

Mr. Scott, the incoming president of the Chamber, welcomed us in a happy little talk. He mentioned that the Chamber would do all it could for the bee-keepers, and in return the association ought to keep a live exhibit (not bees) of honey which had not come out of the ark, in the exhibition rooms of the Chamber of Commerce.

In response, Prof. A. J. Cook said, among many other things, that the fine scenery California bee-keepers always have when in their apiaries should tend to make them good honest men, and he thought they all were. In fact, there can not be many bad people in the midst of such magnificent natural views as we are continually feasting our eyes upon.

California bee-keepers appear to have implicit faith in the National, as our president declared, when urging people to join the association, that the National had never failed to "bust" an ordinance that oppressed a bee-keeper.

During the morning session Prof. Cook took occasion to introduce several eastern people, only three of whose names I now recall—Mr. H. B. Harrington, of Medina, O., Mr. Coggsball, of New York, and Mrs. H. G. Acklin, of St. Paul, Minn., and the convention welcomed us in a body. Mr. Har-

rington was called on to speak, and in the course of his remarks told how Mr. A. I. Root commenced making bee-hives.

There were two evening meetings, at which music, both vocal and instrumental, stereopticon views, and addresses, were the principal features.

Those having papers were: Mr. J. W. Ferree, Newhall; Mr. J. W. George, Imperial; Prof. A. J. Cook, Claremont; Mr. C. M. Richter, Santa Barbara; Mr. J. E. Pleasants, Orange; Mr. Ralph Benton, Berkely; Mr. M. H. Mendleson, Piru; Mr. Joseph Moffat, Los Angeles; Mr. T. O. Andrews, Corona; Mr. G. J. Lynn, San Fernando; Maj. G. F. Merriam, Twin Oaks; Mr. C. A. Wurth, Ventura; Mr. Bishop.

There is a very strong feeling, apparent at all times, in favor of organization and co-operation among California bee-keepers for mutual protection. They claim every other big industry is organized, and why not honey-producing?

There is much uneasiness at present in the southern part of the State concerning conditions around Fresno. Black brood has made its appearance up there with such sweeping and fatal results that every bee-keeper, familiar with the situation, is alarmed. Quarantine resolutions were introduced during the convention.

The former president, B. G. Burdick, of Redlands, was re-elected; also Secretary and Treasurer, A. B. Shaffner, of Los Angeles. The vice-presidents, one from each county, are the presidents of the local societies or clubs. The convention was well attended, and much interest was manifested in most of the subjects discussed.

After adjournment of the State convention the bee-keepers of Los Angeles Co. got together and organized a local society; elected officers, and appointed a committee to wait upon the county board of supervisors in regard to establishing a quarantine against bees being shipped into this county from any section infected with black or foul brood.

Los Angeles, Cal.

## SECTIONAL HIVES FOR COMB HONEY.

Criticisms Come from those Who have not Understood the Special Management Required.

BY LEO E. GATELY.

Previous to the adoption of the sectional hive in my apiary several years were spent experimenting with and testing the merits and demerits of the various styles, in an endeavor to determine exactly what style and depth were best adapted to the exclusive production of comb honey. Its adoption, therefore, was not the result of mere chance or prejudice, but rather because it stands preeminently unequaled in flexibility and economy of management.

In a great many (and perhaps most) localities, some form of contraction is a necessary essential in securing satisfactory

work in the supers. With unlimited skill it is impossible to attract the bees into super work so long as there are empty combs below. In this respect all deep hives, if not utter failures, are at least fundamentally bunglesome. To contract the hives by replacing some of the frames with wooden dummies invariably results in poor filling of the outer sections, and in getting them completed with the central ones. Obviously, the only remedy is to contract from the top, without reducing the supering surface. With a hive in which the brood-chamber is horizontally divisible, the mere removal of one or more of the hive divisions or brood-chambers contracts it to the desired capacity.

The divisible hives in most general use are built to hold the common square section, as they were fashioned to fit the Langstroth frame. My present one was built for the modern 4·5 section, and, like one or two others, the super was first considered in planning its general construction. Again, instead of making the brood-chamber deeper than the super, as is usually done, the hive was cheapened and simplified by making each division one and the same thing in every detail.

Owing to the frequent mistake of having applied the identical methods of management to the sectional hive that has been habitually given to single-chamber ones, it is constantly receiving an endless amount of unjust criticism from those who suppose they have given the matter close investigation. The principles contained in the two hives are radically different, and the most valuable features of the sectional hive are manifested only when proper methods of handling are employed.

Years ago practical honey-producers fully demonstrated the feasibility of handling hives instead of frames. It is possible to determine the condition of a colony by elevating one of these hive divisions and looking between the comb surfaces, as well as the apiarist who tediously goes over his hives frame by frame. With proper management one can thoroughly handle nearly twice the number of colonies that he can when single-chamber hives are being used.

The one redeeming feature of a deep hive lies in its excellent wintering qualities. A shallow hive can never be an ideal winter hive. Let it not be forgotten, however, that a sectional hive is not necessarily a shallow one, but may be made at will of any desired depth.

While, generally speaking, it is advisable to have no more than one style of hive in the apiary, this rule can not always be too strictly adhered to. A divisible hive and a deep one that will tier up perfectly is at times even handier than either when used alone. For instance, when colonies build up sufficiently in spring to require additional room, and the flow has not yet been reached, a shallow chamber will usually give just the correct amount of room to discourage swarming. When the flow appears, these

shallow chambers can be replaced with surplus-receptacles, and be used for hiving swarms or making new colonies. Under such circumstances, two styles of hive go well together, but they must be of proper dimensions to tier up perfectly.

Ft. Smith, Ark.

### STOCKING A BEE-RANGE.

**The Problem of Overstocking; Various Causes of Annual Variations and Marked Changes in the Varieties and Quantity of Honey-producing Flora; is a Range Overstocked When the Surplus per Colony Begins to Decrease? Number of Acres Necessary per Colony.**

BY OREL L. HERSHISER.

How many colonies of bees are required to stock a location properly?

The bee-keeper has a general idea as to the value of a bee-range. If there is an abundance of one or more varieties of honey-producing plants within easy bee-flight of the apiary it is esteemed a good location. But the number of colonies required to work a given area to best advantage has rarely been approximately ascertained. While it is a perplexing problem, probably impossible of exact solution because of the varying climatic conditions, yet there seems no doubt that a much nearer approach to a knowledge of the average annual net possibilities of our locations may be had.

It has been observed that, when a location was supposed to be stocked with as many bees as it could profitably support, afterward the number of colonies has been doubled or trebled without producing any noticeable decrease in the yield per colony. It has been the experience of bee-keepers who thought they had their locations stocked to the limit of profitable production, that some other apiarist, wishing to share in the excellent honey crops of the locality, has moved upon the same territory, sometimes undoubtedly resulting in some decrease in the yield per colony, but often without producing any noticeable difference. On the other hand, it has been noticed that, where the number of colonies in some fairly large apiaries has been greatly decreased there has been no apparent increase in the yield per colony.

The value of a location is not to be determined by a single season's honey crop, and very often not for three or more successive seasons, but from its average annual possibilities as ascertained by observations for a period sufficiently long to give us confidence as to what we may expect. A location may be capable of producing abnormally large crops, but they may occur so infrequently, and be followed by so many seasons of failure, as to make it of no value to the specialist. A location productive of plants that annually yield nectar in abundance is valuable in proportion to the acreage or amount of the flora; and if so limited as to supply a good crop to but few colonies it would be of no value as a field for extensive operations.

There are many kinds of good locations; but all may be classified under two general heads—one wherein a single variety of dependable nectar-yielding plants is abundant over a large area, and which has a long period of blooming, such as clover, basswood, wild red raspberry, buckwheat, alfalfa, sage, etc., or where two or more dependable nectar-yielding plants that bloom at the same time are abundant; the other, where several varieties of dependable nectar-yielding plants that bloom in succession or at different periods of the season are abundant over a large area. Supposing the total amount of flora in the first-mentioned kind of location to be the same as the total from all sources in the latter, the former is capable of profitably supporting the greater number of colonies, for the reason that the honey-flow, while shorter, would be nearly as profitably worked per colony by the greater as by the smaller number of colonies that would properly stock the latter. In the latter kind of location the smaller number of colonies that could be profitably kept would be compensated for by the greater yield per colony, owing to the prolonged honey-producing season.

Since it would be unprofitable to keep enough bees in a location to gather all the nectar as we would harvest a crop of potatoes, corn, or wheat, where we secure practically all that has matured on a given area, we must do the next best thing if we would get the most out of the apicultural pursuit and keep in the apiary the number of colonies, as nearly as we can determine, that will produce the greatest amount of honey at the maximum net profit.

A location is not stocked to yield the greatest net profit if we stop increase at the point where there is the first perceptible decrease in the amount of honey per colony. The number should be increased as the yield per colony decreases until the point is reached, as nearly as may be determined, where the apiary can be operated at the greatest net profit. Thus will the greatest possible amount of God's bounty to the apiarist be made available for the use of humanity.

Suppose A has found by experience that 300 colonies will produce an average annual crop of 60 lbs. per colony or a total of 18,000 lbs.; and suppose B, three miles from A, with 100 colonies on an exactly similar location as to honey-producing possibilities, obtains an average annual crop of 80 lbs. per colony, or a total of 8,000 lbs. It is obvious that the difference of 10,000 lbs., in A's favor, the skill of the operators being equal, is due to his having stocked his location more nearly to the limits of profitable production.

The reasonably frequent occurrence of first-class crops of honey indicates a good location, even if there are a good many seasons of failure. As a case in point, I have in mind a bee-keeper of California having several apiaries in a certain locality, and in a good season the yield is in excess of 100 lbs. per colony. In 1901 there was a first-class crop; in 1902 there was a failure to the

extent that the apiarist expressed himself as being able to "carry his crop under his arm." In 1903 there was a full crop of 100,000 lbs. Within ten to twelve miles of this location there were thought to be 10,000 colonies of bees, as I remember the statement of my informant, which shows the estimation in which the locality was held, notwithstanding some seasons of total failure of surplus.

In 1905 I had 100 colonies in a certain location, and within 80 rods were at least 50 other colonies. Alsike, white, and sweet clover were abundant and luxuriant, and my crop was 100 lbs. per colony, with an increase of 75 per cent. Residing about three-fourths of a mile from the apiary I had good opportunity to observe; and as I had the only considerable number of Italians within several miles, my bees were easily identified. I saw very few of them more than one mile from the apiary, although during the honey-flow they flew from and to the hives in great numbers. The apiary was located in the city where considerable of the area is occupied by streets, buildings, gardens, railroads, and numerous barren stone-quarries. An estimate that one-sixth of the area was covered with an abundant growth of honey-producing forage would be approximately correct; and if the bees flew in all directions the same as they did where I made observations, which was a wide expanse of clover, I am of the opinion that, during the honey-flow, not more than five per cent of them flew more than a mile from their hives, and those not greatly in excess of that distance. The area of a circle one mile in radius is 2010.6 acres; and, if my estimates are not at fault, 95 per cent of my bees gathered their part of the honey from about 335 acres of flora, or about  $2\frac{1}{4}$  acres to each of the 150 colonies on the range. As the area of a circle increases rapidly as the radius increases it will be seen that, by a flight of a few additional rods from the apiary in all directions, a greatly increased area may be reached. Thus while the area of a circle having a radius of one mile is 2010.6 acres, that of a circle having a radius  $1\frac{1}{2}$  miles is 4523.9 acres, or an area  $2\frac{1}{4}$  times that of the circle with a one-mile radius. The bees, by a flight of half a mile beyond the one-mile radius in every direction, would reach 2513.3 additional acres. It seems quite reasonable to believe that bees can work profitably to a distance of at least  $1\frac{1}{2}$  miles; and as my bees and those of my neighbors did not seem to stock fully the location to a radius of one mile,  $2\frac{1}{4}$  times the number or 338 colonies would not have crowded the location; and I firmly believe the number of colonies that could have been worked at greatest profit there that season would have been in excess of 500, or at least one colony to each  $1\frac{1}{2}$  acres of flora. The honey crop at this location for the four preceding seasons was above the average with nearly the same number of colonies. That of the season of 1906 was a failure with the same number; but it is my opinion that, with 10 colo-

nies, the failure would have been nearly as marked.

For the purpose of an analogous comparison, suppose a number of berry-fruit farms aggregating 750 acres, all situated within a circular area three miles in diameter. Suppose an abundant crop of berries. It is evident that with such a crop, and so many acres of bushes, 100 pickers would each be able to gather the maximum number of quarts per day, because it would be impossible for a picker to go carefully over anywhere near  $7\frac{1}{2}$  acres, the proportionate area of each, as fast as the fruit ripens. With a stint of  $1\frac{1}{2}$  acres each, assuming that 500 pickers is the approximate number required to gather the fruit with greatest profit to the growers in the average season, it is evident that each could still gather the maximum amount when there is an abundant crop. Assuming two acres to be all a picker could possibly attend to in a season of less than the average crop, when no picker could possibly gather anywhere near the maximum, no matter how much area was allotted to him, very little advantage to the individual picker would accrue by the employment of a less number than is required in the average season. This is evident from the fact that, when the fruit is thinly distributed, and of small size, the picker's time is largely taken up in searching over a large area to gather a given quantity.

Let us now assume that 750 acres of this circular area is a first-class alsike-clover or other good honey-producing range, and that a bee-keeper resides in the center so his bees can reach every part of it with a flight of not more than  $1\frac{1}{2}$  miles. Assuming that  $1\frac{1}{2}$  acres of flora per colony is the area that will yield the greatest profit in the average season, from analogy it is clear that neither 100 nor 500 colonies would overstock it, and much less would they do so in a season of bountiful crop. On the other hand, in a season of failure of surplus there would be only a slight overstocking, wherein the small loss would be insignificant as compared with the great gains of the average and bountiful crops. In the medium season the larger number would prosper nearly as well as the smaller, because  $1\frac{1}{2}$  acres of thickly growing honey-producing flora would undoubtedly be as much as the average colony could work; and when it comes to nearly a failure of nectar secretion, the larger number would show only a slight falling-off, for the reason that the time of the bees is nearly all consumed in flying from flower to flower in the almost fruitless search. This statement is impressive when we remember that apparently, in the season of 1909, we had the most luxuriant and abundant basswood bloom we ever saw that certainly promised a bumper crop, but there was never a smell of basswood honey in the hives.

Further confirmation of the proposition that, in a season of scarcity of nectar secretion, a few colonies in a normally good location will do very little better per colony than the number that would properly stock

it in a good season, is found in the fact that in a poor season the bee-keeper with a few colonies is found to have a "short crop," and is "obliged to feed," just as is the apiarist who operates on an extensive scale.

It is well to bear in mind that annual variations and permanent changes in the amount, area, and varieties of honey-producing flora have occurred and will continue to occur in nearly every locality. These variations and changes are traceable to two prime causes: viz., to the absence of uniformity in those conditions that go to make up the climate, such as heat, humidity, precipitation, winds, clouds, and electrical conditions; and, second, to the hand of man; i. e., to the operations of the lumberman and husbandman in the destruction or production, as the case may be, of honey-producing flora.

Kenmore, N. Y.

### GIVING INDOOR FLIGHTS TO BEES DURING THE WINTER.

BY G. T. WHITTEN.

On Dec. 16 I transferred a strong colony from a ten-frame hive into an eight-frame glass hive, the change being made out of doors, the temperature  $34^{\circ}$ . The bees were all in the new hive in about 20 minutes, when they were taken inside and placed in a south window in a cold room, and given a flying-cage two feet square, the hive entering the cage at the back, with an entrance out of doors through the cage.

Feb. 19 they were moved into a warm room and given a flying-cage the same as before. The temperature of the room was from  $60$  to  $70^{\circ}$ .

March 4 the hive was placed on top of a new circular hive. The bottom-board was removed to give the bees a free passage down through the lower hive and out into the cage.

March 12 the bees with the queen were all smoked down into the lower hive, and the top hive removed. They were then given a frame of honey from the original hive, this being placed in the cage. They at once made themselves at home and began building comb, filling it with honey from the frame. This hive is made on the plan of a half-circle, with glass on all sides.

The frames are of standard size, and are placed long side up, and so arranged that they can be turned around in such a way that each frame stands at right angles to the next one, thus giving an opportunity to see every movement of the bees on the frames. The frames contained only foundation of different dimensions, from none to full sheets. They are now, March 23, working on six frames, and have them well filled.

The second day they prepared a brood-nest, and the queen commenced to lay, and continues to do so. The frames are opened from once to many times each day for inspection. This does not appear to disturb

the bees in their work. They are looked over each night, a careful examination is made, and a record is kept of the changes during the day.

The bees are hybrid, very black. When outside they were very cross; but since being inside they have become gentle, and can be handled almost as safely as flies. They appear to enjoy being on exhibition.

The hive, with the brood and stores from which the bees were transferred, was taken to another room, and given to a single-frame colony that has been kept in a warm room since June 14, 1908. The frames were spread apart, and the frame with its bees and brood placed in the center of the brood-nest. The changes have been very successful.

Hartford, Conn., School of Horticulture.

### A NEW HONEY-STRAINER.

A Combination of Two Vertical Straining Surfaces which will Handle the Honey as Fast as it Runs from the Extractor.

BY R. F. HOLTERMANN.

Some years ago I described a strainer which I had been using for some time—one which was built in the extractor. This acted automatically, the honey flowing through it as fast as extracted, before it had a chance to cool. During the process the honey was

bles which produce the froth and scum, on which there is so much debate. Such troubles have been practically unknown to me since adopting this method of straining my honey.

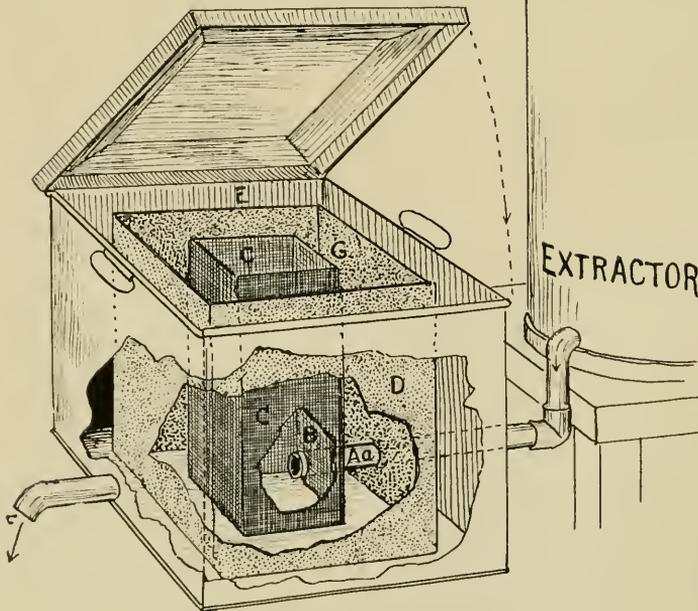

Since the publication of my first plan, p. 146, Feb. 1, 1906, others in the United States, and even in Europe, have used it. The great drawback preventing its general adoption, however, was the fact that the strainer was attached to the inside of the extractor, and could not well be attached to an extractor already in use, as a special construction was required. To overcome this objection I have devised a new form of strainer, retaining all the principles of the previous machine, with the addition of a second strainer; that is, there are now two strainers—a coarse one and a fine one, the coarser one relieving the finer from clogging. The pressure and straining surface are increased in proportion to the depth of the honey in the extractor.

As shown in the illustration, the honey, after being thrown from the combs, strikes the side of the extractor and runs down to the honey level in the extractor below the reel. From there it flows out through the gate or through a special opening into the strainer-tube, which is connected with the strainer by means of a rubber hose. The honey then, by means of a 2½-inch-square tube, Aa, flows into the central compartment of the strainer B. Here, partly by means of

gravitation, as in the former construction, and also by means of the wire cloth, twelve meshes to the inch (strainer C), the coarser particles are separated from the honey, which, in its outward course, then reaches the finer strainer, D, which is cloth supported by coarse wire cloth, like that used for the comb-pockets of extractors. Through this cloth it flows into the outside space, E, and from thence through the opening F, into the barrel or other container.

The cloth strainer, D, has a capacity of 1700 square inches. Most of the larger particles in the honey, owing to gravitation, never touch the cloth, because they are retained in the

central compartment; and the bulk of those remaining rise to the surface of the honey and find their resting-place, not on the side of the cloth, but on the bottom of the can. Let me say, however, that, unless

HOLTERMANN'S NEW STRAINER.

not lowered below the honey-gate of the extractor, and it did not need to be lifted up later by main strength. The honey flowed in an unbroken lateral flow, so there was not the objectionable admixture of air-bub-

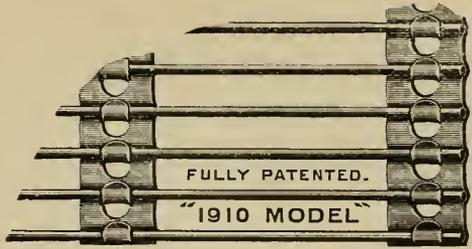

the honey is passed through the strainer at a much slower rate than is practical, I would not consider it safe to depend upon gravitation alone, for even water will carry along its course particles which, by the law of gravitation alone, should sink to the bottom or rise to the top; and a thick substance like honey has a much greater tendency to carry with it such particles.

The coarse wire strainer has four sides, 9 inches in width by 24 inches high. This is as coarse as will answer the purpose. The cheese-cloth strainer also has four sides 18 inches in width by 24 inches high. If the space under the baskets of an extractor is of a less depth than the straining-can, the entire surface of the strainer can be secured by lowering the bottom of the strainer below the bottom of the extractor.

If the weather is cold, or if the honey has been allowed to cool in the combs, the rapidity of the straining can be hastened by means of an oil-stove underneath; but the above system strains the honey under the best possible conditions without artificial heat, and I have rarely found the heat necessary.

The strainers can be removed from the can, as they are secured to the bottom by means of corner posts and cotter pins. The cheese-cloth is passed under the wire-cloth form upon which it is stretched. There is a valve by means of which the openings A and F can be closed at will. The valves are constructed in a manner similar to ordinary screw-cap honey-gates, and are operated by means of handles extending up to the top of the can.

Brantford, Ontario, Canada.

This excellent appliance is made from special hard-drawn round wire that *will not rust*, and is much in advance of the zinc one. The inventor claims the following points; and from my own personal experience I can endorse his opinions:

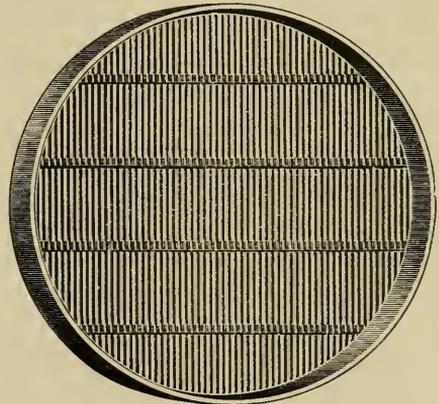

Twelve hundred bees can pass through at one time in a ten-frame hive,  $\frac{3}{8}$ -inch top-bars, as against 800 with the zinc excluder.

It presents a smooth rounded surface to the bee, instead of a knife-edge.

It will not buckle, and there are no flat surfaces to be sealed down.

The five ribbed strips,  $\frac{1}{8}$  in. wide, rest on the top-bars of the frames, from end to end.

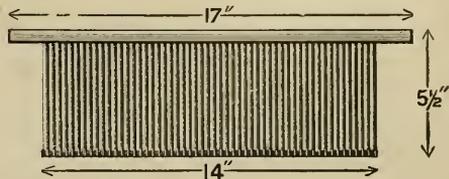

The bees pass through with scarcely any hindrance at all, which is invaluable to queen-excluders. It checks swarming to a great extent.

PATENT

QUEEN AND DRONE RIDDLES.

These are very useful in driving or shaking bees from their combs. They can be put to many useful purposes in the apiary. It allows workers to pass through, leaving the queen and drones to be disposed of as desired.

PATENT

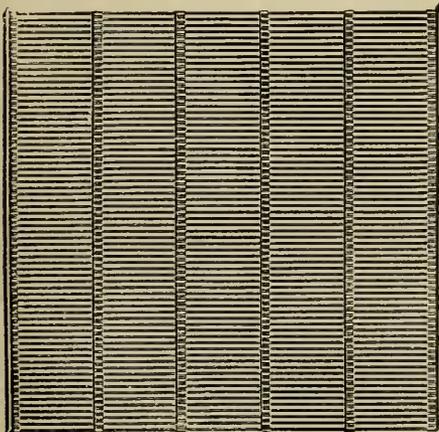

FRAME-DIVIDER.

WIRE QUEEN-EXCLUDERS IN ENGLAND.

BY JOSEPH TINSLEY.

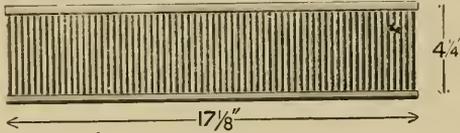

I am sending particulars of some novel inventions by a bee-keeper in this part of the country—a particular friend of mine, Mr. Arthur H. Wilkes. I will first mention

THE FREE-WAY QUEEN-EXCLUDER.

PATENT

A simple appliance for insuring heavy frames of honey having flat and even surfaces either side. Bee-keepers know the time saved in uncapping honey when the combs are built evenly. By using this appliance the work is performed in half the time, and reduces waste to a minimum, as the cappings may then be shaved off in one complete piece. Frames of honey built by the aid of this ingenious appliance present a most attractive and splendid appearance for exhibition at shows or shop windows.

PATENT  
WIRE SECTION-SEPARATOR.

The great point in favor of this class of separator is that it allows the bees plenty of space to work, and gives free access to the sections. Being non-rusting it will last for years.

Stone, Staffs., England, Jan. 20.

[This is certainly a novel way of constructing wire queen-excluders; but in our opinion the plan is defective in one respect. For instance, in the sample sent us the wires are held only approximately the same distance apart, the spaces varying from about 164 thousandths to more than 175 thousandths. A good many queens would certainly get through a space as wide as the last mentioned. Wire excluders as made in this country vary scarcely 2 thousandths of an inch — 163 thousandths being the standard.]

The trouble with this method of making wire excluders will be understood by referring to illustration at the top of the right-hand column on the previous page. The spurs punched out of the solid metal, when folded over the bars of wires, are not folded over alike, making the spacing unequal. This may be due to different temper or thickness of the metal, or to defect in the dies. In the second place, the wires are altogether too small in gauge. They should be much heavier. The same principle, patented in this country, is much better, because the wires are made of thicker gauge, and held apart by molten metal poured around them at certain intervals.—ED.]

## HOW TO FEED ARTIFICIAL POLLEN WITHOUT EXCITING THE BEES.

BY JOSEPH GRAY.

F. Dundas Todd, p. 122, Feb. 15, touches a subject of intense interest. It involves a far wider question than pollen feeding, which, to me, is one of the simplest matters of apiculture, and I was somewhat surprised to see his failure in hunting up the matter.

A close observer will not be long in discovering that the bees store their pollen in the comb next to the brood, and it is a big mistake to remove such combs in spring-time; if, then, our colony is short of pollen this is the place to give it; and so simple is the method that I thought it was a well-understood detail of bee-life. What I do is to take out the comb next the brood, dredge it well with meal, not fine flour, and replace it. By this method the bees are not unnecessarily excited, which is the one thing to avoid in unsuitable weather.

We all know the brood-nest advances slowly at first, and, if a queen is short of bees, to cover her work she will cross and recross, laying as many as five and six eggs in the same cell rather than go outside the cluster of bees. Old combs add to the warmth of the brood-nest, and usually contain pollen store, and are, therefore, of great value in the early spring.

The real reason so little is said on pollen feeding is that a district short of early pollen is the exception, not the rule. You can not force nature so early; wait till the crocus and willow are in bloom; and after the brood-nests are well going you can force on the strongest first, and make them feeders for the weak ones.

### WHY CAN WE NOT FORCE EARLY?

Flight in unsuitable weather brings disaster to our little aviators; a chilling blast, a broken wing, means death to the busy worker; so the using of pollen, which means a larger amount of faeces to void on the wing and the bringing-in of water to prepare the milk food for the brood progresses only with the progress of the outside conditions; as these advance in warmth and sunlight, so the brood-nest advances; and as it advances, then and not till then can we force the pace. It is not profitable before, for the loss in bee life is not compensated for by the amount of brood raised. Never use a method of giving early pollen by which the bees are compelled to take it, because if they use more pollen they must fly more to rid themselves of the extra faeces.

Brood-nests advance in spring in proportion to the number of bees composing the stock. A weak stock may be headed by an extra fine queen, but not enough bees to cover her work. I have counted in one case cell after cell with ten eggs in each cell, and in some cases two larvae in a cell. Keep such stock until you have built the strong stocks; then on a *flying day carry sealed brood and nurse bees*, and strengthen and equalize the apiary.

Never give brood alone to a weak stock; if it could have cared for more brood the queen would have seen to that. Far wiser is it to take one comb of brood and nurse-bees to a weak stock than two combs of brood which are liable to get chilled instead of strengthening the stock.

Dumbarton Road, Glasgow.

## Heads of Grain

*from Different Fields*

### WHITE CLOVER CAUSING BLOAT IN CATTLE. MOSQUITOES LARGELY TO BLAME; SALT PORK RELIEVES BLOATING.

I seed a fresh pasture each year. I have sowed for pasture a mixture of timothy and mammoth red clover; timothy and red clover; timothy and a mixture of red and alsike clover. The past year, my pasture being of timothy, alsike, and red clover mixed, the alsike seemed to occupy the ground entirely, and the bloom period lasted for a long time. The pasture looked beautiful, like large pink snowbanks. The milk supply was larger than when I pastured on either of the other clovers; but I was troubled much more with bloat than during the previous seasons, when I pastured on mammoth red and common red clover. Of course, the alsike was of a much heavier nature. This is how I account for the larger milk supply, and also more bloat. I think the large stems of the mammoth helped to a great extent to prevent bloat. Likewise, if white clover makes sufficient growth it will produce bloat.

Clover, at least with me, is not the only cause of trouble. Cows will not bloat if allowed to fill themselves with other grasses before going on the clover. Then, even though they are kept there, there will be no trouble unless in some way they are prevented from eating. This is where my trouble lies; the mosquitoes, at times, when the weather is wet, are very bad. The cows are hungry in the morning, after a long night's fight; and when the sun rises the mosquitoes quit their work, and the cows go to eating voraciously; and then it is not long before I have a case of bloat. I have never lost a case so far. I get a chunk of salt fat pork and shove it down into the mouth of the cow as far as possible, and at the same time hold up the cow's head by putting my other arm up over the neck and down under her jaw. I lift up to prevent her dropping the fat pork. She will chew for a while, and soon swallow. This will relieve the case at once.

I wrote to the Minnesota Experiment Station, asking if they knew of any thing I could spray my cows with to prevent the mosquitoes from tormenting them; but in reply they said they knew of nothing but kerosene. I did not place much confidence in that. I think that, if we had something in the form of grease, or something to spray the cows with, our bloat trouble would almost be at an end.

Medford, Minn., March 7. J. F. BRADY, JR.

### A JACK-KNIFE OPERATION TO RELIEVE BLOATING.

I have raised considerable alsike, both for hay and pasture. I always let cattle out both night and day so as to prevent them from getting too hungry. I have had bloat but once, and the circumstances were these: A wet spring caused a very rank growth of alsike; and one hot morning about the first of June, when the alsike was five or six inches high, the cows, for some reason, stayed in the yard until about 9 o'clock, and, I think, drank quite heartily just before going out. In about an hour they came in again. Two were bloated—one old cow very badly, and a young one not so much. An old man had told me once to put a large wooden bit in the animal's mouth, and the efforts to dislodge the bit would enable the gas to escape. I tried that first on the old cow, but it did no good, and in the few minutes I was working with her she was rapidly getting worse. I had no trocar and cannula; but I thought she would die if I left her alone long; so I pulled out my jack-knife with a sharp-pointed blade about  $\frac{3}{8}$  inch wide, and, holding the blade very firmly between the thumb and first finger, letting it project about an inch, I jammed it through the hide up to my fingers, on the left side, half way between the hip bone and the first rib. I found it necessary to put something in the way of a tube in the hole, as it will close when the animal moves, as the inner linings will move over the hole in the skin. So I put in a piece of quill from a large leather, and in a short time the old cow was almost as well as ever. I noticed, however, she showed the effects for a week or ten days, after which she was

all right, and I owned her and pastured her in the same field for several years.

While I was operating on the old cow, the young one that was not bloated so much began to go down, and recovered without any treatment.

I regard alsike as a much superior feed to white clover, and I should not worry over the bloating, with this precaution: Never let cattle get very hungry and then fill up on a rank growth of succulent feed like alsike, and especially if it is wet with dew or rain. As Mr. Goddard says, "When cattle eat heavily of any succulent crop they are subject to bloat."

Dunlap, Ia.

E. S. MILES.

### WHITE CLOVER CAUSES BLOATING WHEN IT GROWS VERY RANK.

About 1878 to 1886 it was a common thing for the cows to become bloated on white clover in and around Wyandot, Kansas, where I then lived—that is, the cows that were turned loose on the commons in our little town. Many cows died from it. The clover was very rank, some years being nearly knee-high in many places. When the dew was very heavy I used to keep my cows up in the morning until the clover was dried off. I have put a gag in the mouths of two or three cows until they would belch the gas out.

Escondido, Cal., Feb. 24.

J. A. NELSON.

### FEED HAY BEFORE TURNING ON TO CLOVER.

I think the cases of bloating from alsike or white clover are very scarce, but from red clover, very frequent. Bloating might take place from the small clovers if there were a large growth, and hungry cattle turned on when the clover is wet or frosted. The best way to avoid bloating is to turn cattle on when the grass is dry, or for only a short time, say two hours; then drive them off for the day. In all cases of that kind it is better to give cattle a good feed of hay; then when the grass is dry they will not overload their stomachs.

Easton, Md., March 10.

J. AIKENHEAD.

### ANY CLOVER MAY BLOAT CATTLE.

All clover will bloat cattle when they are turned out on it before the dew dries off. I have never lost any stock from that cause, but I have had some swell up until they were ready to burst. My remedy is a teaspoonful of epsom salts and a tablespoonful of ginger put into a bottle afterward filled with water. Shake well and drench, and watch the cow chew, as if chewing the cud. When she is done she will be the poorest-looking skeleton you have seen for some time. Where the flesh goes to I can not tell.

Marshallton, Pa., Feb. 22.

W. W. WEBSTER.

### A SHORT PIECE OF GAS-PIPE INSERTED AS A BIT AL- LWS THE GAS TO ESCAPE.

White clover does cause bloat. We have had experience with that and red-clover bloat. In 1908 white clover was abundant, and we had considerable trouble. To cure bloat, take a short piece of gas-pipe and drill a few holes through it and place it cross-wise in the animal's mouth like a bridle-bit, and, nine times out of ten, the animal will soon be relieved. For those who have no gas-pipe, a hollow stick of wood about the size of a broom-handle, with holes bored through, and fastened in the animal's mouth, will do. This allows the gas to escape out through the tube, and prevents the animal from swallowing it again.

Blue Mound, Ill., Feb. 21.

M. C. MORGAN.

### DISTANCE BEES FLY FOR NECTAR.

In this locality my experience says most emphatically that the great bulk of the honey is gathered within one mile of the hive. In one small yard of 25 colonies, only two miles away, the bees during the past summer gathered quite a little surplus at a time when those at the home yard were doing nothing, and they brought in a different kind of honey from any ever gathered at home. Then at the time of heartsease bloom they did not gather as much as the home bees, although they were apparently near more heartsease than those at the home yard. Then, again, a yard three miles from home, and within half a mile from large fields of heartsease, stored several times as much per colony as the home yard, which was from  $\frac{1}{4}$  to  $\frac{1}{2}$  to the same fields. The home bees nearly all flew in the direc-

tion of this heartsease, which was along an overflowed creek-bottom; but they did not seem to get much. Another thing I noticed, the bees that were near the heartsease-field bred stronger in the fall, and were much stronger in bees than those that were further away. It seemed as though the latter knew their forage was far away and hard to get, and they filled up the brood-chamber heavier than the others, and that, of course, cut down the surplus somewhat. The country they have to go over is not very rough—just one large hill, then a straight shoot of about a mile to the bottoms.

Dunlap, Ia.

E. S. MILES.

#### TWO RECIPES FOR USING HONEY.

For honey candy take one cupful of butter, two of granulated sugar, two of honey. Select a deep preserving-kettle and put in the butter, first rubbing it well over the bottom of the kettle; then add the honey and sugar. Let it boil fast for ten minutes. Ascertain if it is done, in the following way: Have ready a cup of cold water, and drop a little into it from the point of a knife. If it is sufficiently done when you take it from the water it will be crisp. Now prepare a large shallow tin or pan; rub over with butter to prevent its adhering; pour from the kettle to get cold. To keep good it should be excluded from the air.

#### BROWN BREAD.

Three cups of graham flour;  $\frac{3}{4}$  cup of honey; 1 pint sour or sweet milk;  $\frac{1}{2}$  cup raisins; 1 teaspoonful each of soda and salt. Grease three 1-lb. baking-powder cans and fill with the mixture.

W. W. APLEBY.

[We have tried both of the above recipes and can vouch for their excellence, the brown bread being especially good. The candy is like the old-fashioned "butter-scotch," but better.

Honey is not used as much as it should be in cooking. It is not as cheap as some of the inferior "corn syrup," but it is not in the glucose class. Honey is sweet, and the so-called corn syrups are but slightly so except for the addition of the 10 per cent of cane flavor. The 90 per cent (glucose) is about half as sweet as sugar.

Dr. Miller and others have given some very good recipes using honey, but there ought to be many more. Our columns are open. Let those who know of good recipes using honey send them in to us. We shall be glad to use them for the benefit of all.—ED.]

#### WHAT IS THE LIFE OF A WORKER?

I have just read Dr. Miller's Straw and your comment in regard to the length of the life of a worker-bee, in which the doctor figures, and you agree with him, that the average life under normal conditions is 6 weeks or 42 days. How this piece of foolishness ever got into bee literature is more than I can comprehend. Not only is the average of the bee's life not 42 days; but the very limit of bee life under normal conditions does not exceed 27 days.

Some years ago I lost heavily in winter, so the next spring I sent to Florida and bought 50 queens. As these were very yellow, and as I used hybrids to form my nuclei, it was easy to see when the new bees began to hatch out, and to see when the last of the old bees were gone. Now for the results: As these nuclei all contained freshly laid eggs it was just 21 days when the last hybrid bees were hatched out. In 27 days more, not one of the hybrid bees was left in the 50 nuclei. Now, if every hybrid bee was gone in 27 days after it hatched, how can you make out the average life of the worker 42 days? I think it is time this inexcusable blunder in bee literature was corrected.

I have been with the bees for forty years; and my observation is that, when the bee begins work in the field, its days are numbered. Of course, bees thrown out of normal condition will live for several months. You may figure from the time the egg is laid; but even then the limit of bee life would be 48 days; but you can not do this fairly, any more than you can figure the life of a chicken from the time the egg was laid, or your own life from the time you were conceived.

Hop Bottom, Pa., March 8.

G. A. WRIGHT.

[A good deal depends on what you mean by "normal conditions" and "average life" when we figure on the number of days that bees will live. Then we must also take into consideration the strain of bees and the source of nectar. "Normal conditions" we would consider to mean the entire season

—beginning, say, the first of May, and ending along in September or October. A heavy honey-flow, especially from some sources of supply, would mean an abnormal condition. When we speak of the "average life" of the bee we may refer to the life during the honey-flow, but generally mean length of days through the entire season.

You are basing your observations on one season's experimenting. In drawing conclusions, one experiment could hardly be considered as conclusive. You say nothing about the kind of honey-flow that was on at the time, nor do you say whether the nuclei in question contained the proper proportions of nurse bees and fielders.

Years ago, when we were Italianizing our apiary, we had an excellent opportunity for observation. We found that, during the height of the honey-flow, the life of the average worker was from four to six weeks—that is, the ordinary black bee. When we Italianized after the honey-flow there were black bees in the hive—large numbers of them—throughout the entire late summer and fall. In some instances the black fellows showed up all winter, but these were exceedingly rare. We remember that the results we secured were quite in line with reported observations of some of the eminent investigators of years ago. On the other hand, we have had reports of where the workers lived only two or three weeks. In that case the bees had to work on sources of nectar supply where it was very difficult to get the coveted portion of nectar. Some flowers are of such construction that the bees have to do a great amount of crowding and straining to get down to where the nectar is. In that case the wear on the wings is excessive. The life of the bee depends very largely on the wings. If the wings are worn or frayed out, the whole bee will be out of commission. We have almost a parallel case in the horse. He will be able to do good service so long as his teeth hold out; but when they fail him, so he can not masticate his food properly, he is soon good for nothing. We shall be glad to hear from others on the question.—ED.]

#### PUTTING FRESH BEES ON COMBS ON WHICH OTHER BEES HAVE DIED.

A lot of my bees died this winter and I have a lot of old combs filled with bad honey which is candied or granulated. I have no extractor. Would you tell me how to get it out of the comb? Can I feed the honey back to the bees when they are raising young bees, as the honey is soured and the comb is moldy?

Tidal, Pa.

JOHN A. WOLFE.

[There is no trouble about putting bees on to combs from which other bees have died, providing the stores have not soured. If they are sweet, even though candied, the bees will use them providing they can get access to water. If the honey is actually soured, there is not much you can do with it except to soak the combs in warm water, extract the candied honey partially soured, then work it over into honey vinegar. If the combs are undesirable in other respects we would advise putting them through a wax-extractor. The melted wax will be on top of the soured honey. When the wax cools, the honey can be drawn off and thinned down with water and made over into honey vinegar.—ED.]

#### CAN THE PRODUCTION OF WAX BE MADE PROFITABLE? THE SIMPLEST AND EASIEST WAY TO INTRODUCE.

1. How would you manage a large colony during a season to secure the largest production of wax from it, instead of honey or increase?

2. What do you consider the safest way to introduce one dozen queens to hybrid colonies during apple bloom?

Crawfordsville, Ind., March 12.

W. H. KERR.

[1. Wax production can not be made profitable in any except tropical countries. Certainly it could not be made to pay in Indiana or any of our Northern States. Even in Cuba, with its long honey-flows, Mr. C. F. Hochstein, a resident of the island, and one who has tested the proposition, says that honey at even one cent a pound is more profitable than wax at 30 cents. On the other hand, wax production on some of the Hawaiian Islands is fairly profitable; but the conditions there are much more favorable than in Cuba or in any of our Southern States. In Hawaii, combs are built from mere starters. The honey is extracted, and the combs

melted up in a special steam and hot-water wax-machine. It is possibly true that a large-sized solar wax-extractor might be employed for this business to advantage; but if we are correct they are not used in Hawaii.

2. We know of no better way for the average person to introduce a queen than to use some good introducing-cage so constructed that the bees can release her automatically by eating out a plug of candy. There are other methods that are good; but this we consider the simplest and quickest to apply.—ED.]

#### WHY IS THE PARENT COLONY LAZY?

We all know that, when a colony swarms, the old queen leaves the old hive, where a new queen hatches, with the larger portion of the worker bees; then a period of depression reigns in the old hive for quite a long time in some cases, and with the frequent result that the new stand in the old hive does not gather very much, if any, more than they are apt to need for winter stores. It appears to take them the rest of the season to recuperate from the effects of the leaving of the old bees. Now, may we not counteract this condition, and cause the parent colony and young bees to store nearly if not altogether as much as the old bees with the old queen, although the old bees and queen store sufficient for themselves and our money-making surplus so much talked of. How is it that a new queen and new bees, with hundreds hatching every minute, can not do nearly as well as the old and almost worn-out colony? Is it possible that the very act of swarming so depletes the vitality of the colony as to necessitate the rest of the season to recover from the effects of the same?

Chadron, Neb., Feb. 8.

LEE CARD.

[There are two or three reasons why the parent colony does not equal the performance of the swarm itself. First, by the time the young hatching bees are *old* enough to gather honey the honey season in most localities is over. Second, the parent colony has given all its working force and many of its young bees to the swarm; and even if all brood of the parent colony had hatched, and the bees from this brood were old enough to go to the fields, its force would be light in comparison with the force in the swarm. There may be a virgin in the hive at the time the swarm is cast, and there may be only ripe cells. At best there will not be a *laying* queen for a week. There will be, therefore, a gap of seven or eight days in brood-rearing, while brood-rearing will commence in one or two days in the swarm. The latter, from every point of view, has all the advantage.—ED.]

#### ANOTHER CASE WHERE PART OF A LOT OF HONEY SOURED.

On p. 74, Dec. 1, mention is made of part of some honey that soured while the rest did not. I had the same experience, only my honey was three years old before it showed any signs of souring. Out of ten cases there were only four that did not sour. It was old honey that I had taken out in the spring to give the bees room. It was strained into a 1500-lb. tank, and then drawn off into 60-lb. cans. It stood in my shop, where it was good and dry; so last spring I thought I would ship it and get something out of it, as it was very dark, and what we call far-weed honey. It was very strong. When I opened the cans of honey they spewed right out; others were all right. I tasted it, but it did not taste sour. I could not think what was the matter with it, so I sent it to San Francisco. The commission man kept it about eight months, and then wrote me he could not sell it; so I paid the freight both ways, and am going to feed it to my bees. Do you think it will hurt them?

Arroyo Grande, Cal., Dec. 1.

M. D. PRICE.

[We would not advise feeding any soured honey to bees under any conditions. Soured honey is good for nothing except to make into vinegar. If the honey is only very slightly sour, bring it to the boiling-point to prevent further fermentation, and give it to bees in spring or summer for brood-rearing. We would not give it in the fall.—ED.]

#### FEEDING POLLEN INSIDE THE HIVE IN SCOTLAND.

I was interested in your reminiscences of the days of auld lang syne in your reply to Mr. F. Dundas Todd, p. 123, Feb. 15, on the question of feeding pollen in hives. We practice three separate plans in

this country, although, as a rule, the pollen supply comes early enough to set the bees breeding. The large majority of British bee-keepers are engaged in the pursuit on only a small scale—indeed, with most it is more of an avocation than a vocation; hence, as with most hobbies, it takes up an undue proportion of their time; and as soon as spring appears they must be stimulating. To meet the want, several of our appliance dealers list a special feeder, with an apartment for pollen as well as one for syrup. The bees can, therefore, get a supply of nitrogenous as well as non-nitrogenous food inside the hive in early spring. Then they advertise candy cakes, of one or several pounds, made from sugar or sugar and honey. Into this preparation, before it sets, they stir a quantity of common flour, rye meal, or pea flour, as a substitute for pollen. Indeed, a very considerable trade is carried on in this line every spring.

A rough-and-ready but very effective plan is to make a thin paste of pea flour and honey. Work it well and press it down into the cells of a tough worker comb. Place this comb next to the cluster, flat above the frames, or lying on the floor-board if there is a deep bottom space. Bees can then start breeding with a full supply near at hand. As, however, water is an utter necessity when brood is being reared, and bees must fly for it, it is questionable whether all this stimulation does much to advance the prosperity of the colony unless in an emergency.

Ballindollock, Scotland, D. M. MACDONALD.

[The fact that bees need water in brood-rearing makes it advisable, when giving artificial pollen, to feed it *outside*; that is, make the bees *fly* for it. If they then can get at the meal they can also get water. For this reason we have discouraged giving nitrogenous food in the hive, mixed either with candy or syrup.—ED.]

#### YELLOW SWEET CLOVER.

Will you please tell me how and when yellow sweet clover should be sown? also the amount per acre. Will it make good hay, or is it to be used only to plow down for fertilizer? Will it grow on wet soil?

Abion, Pa.

W. H. KLINGENSMITH.

[Yellow sweet clover should be handed the same as the white. We have been in the habit of recommending sowing the seed in about the same way, at the same time, as common clovers. It may be sown with any kind of grain; and if it does not come up right away it will later—that is, if conditions are favorable.

No one ever needs to be afraid of any of the sweet clovers being noxious weeds. They will readily yield to the plow. Plow under as you would common clover, and for the same purpose, and there will be no more of it in that field except, perhaps, around the fence-corners or in waste places.—ED.]

#### RAISING QUEENS OVER STRONG COLONIES OR IN NUCLEI.

I know the latest system of raising queens and am able to produce them successfully. If I form a nucleus over a strong colony with *wire* cloth between the colony and the nucleus and get a queen fertilized and laying in the nucleus, and then kill the queen in the old colony and remove the wire cloth, will the new queen in the nucleus be accepted by the bees in the old colony? Is this a safe way to requeen? Or would it be better to raise the new queen in a nucleus and introduce her from a cage with candy, the orthodox way?

Mount Airy, N. C.

J. E. JOHNSON.

[Your plan will work, but we would not advise raising queens on this plan. Generally speaking, after the cell-building stage queens should be raised in nuclei on separate stands.—ED.]

#### FOUNDATION TEN YEARS OLD STILL PLIABLE.

I have just been using some Weed foundation I bought of you in 1900. It is as soft and pliable as the day it was made, and as tough as parchment. I see no reason why it should not be as good after fifty years as it is now.

Fernhill, N. Z., Jan. 3.

O. R. BOSTOCK.

[This is contrary to the lately expressed opinion that foundation should always be fresh. It would be interesting to know whether the bees were able to draw it out as easily as they would the fresh.—ED.]

## A LARD-PRESS FOR RENDERING WAX.

Having some wax to render last spring I soaked my combs well in water and heated them up to the proper temperature. I arranged an Enterprise sausage-stuffer and lard-press as for lard-pressing; and, having made a sack of good burlap of a size a little larger than the inside of the press I dipped my melted comb and wax into it and pressed it as dry as I could; then I took the sack out and put it back in the water and melted the wax. I took the top of the sack in one hand, and with a stick in the other I punched and stirred the sack until it was all softened up again, then I put it back and pressed it again and got the wax out in fine shape, as good, apparently, as a wax-press would have done. The lard-press is something that almost every one has, and it does not hurt the press, and saves buying a wax-press.

Dayton, Va.

S. H. BLOSSER.

[There is no question that you can render wax in a lard-press; but unless you repeated the alternate heatings and pressings a number of times you would be sure to lose some wax in the slungum. Unless you had a small amount of comb to render, you would probably find that you would lose enough in a short time to pay for a good press adapted for pressing combs.]

When you wish to heat up the contents of the sack again, dip off the layer of wax on top of the water, else the slungum will quickly absorb some of it, making it necessary to do that much of the work over again.—Ed.]

## WERE THE DRONES WINTERED OVER?

I noticed one of my colonies, a strong one, in normal condition, that had drones flying which must have wintered over. I watched to see if they were kindly received upon reëntering the hive. This they were. A wasp trying to enter the hive was given a warm reception.

I introduced alsike clover in this locality, with the result that it gets sown more and more every year. I have been thinking of sowing sweet clover along the railroad-tracks. What variety would you advise me to sow? Several years ago I sowed a small end of it to the yellow kind, and a little of it to the white. The white always gets mown off before it gets in bloom; but the yellow does not. I would rather sow the white, so as to have something for the bees when grapes and peaches ripen; but I am afraid it will get mown down before it gets to blooming, on account of its tall growth.

H. STOCK.

Augusta, Missouri.

[Drone brood will sometimes be reared in late winter or very early spring. This is particularly so if the queen is old or failing. These early-hatched drones are quite apt to give the impression that they had been in the hive all winter.]

We had one hive in our north yard that had quite a bunch of young drones by the first of March. One might easily suppose that they wintered over, just as you did. Of the two sweet clovers, the white is superior, and the yellow hard to get. You can sow sweet clover along the railroad banks; but you had better get permission from the company. Public sentiment (based, of course, on ignorance) would be against sowing sweet clover in waste places; but the public is being educated through progressive farm papers that now know that the plant is not a weed but a valuable forage-plant. It is a great soil-binder for railroad embankments, and it won't be long before these great thoroughfares will sow the seed themselves for the protection of their property. When farmers, too, welcome it we shall expect a greatly increased source of honey. May the day speedily come.—Ed.]

## STINGING NOT FATAL TO CATTLE.

On 14, 1899 Mr. J. F. Semper inquires about bees stinging stock, and then the stock died. If that is the case I should have some terrible damages to pay. I live in quite a dairy district. Last season I wintered 130 colonies here. When the warm days came on, bees went in search of pollen, and they got into the dairymen's gluten-feed bins, and then into the feed-troughs. The cows would cough and gag and kick, so the men could not milk the cows till the bees quit flying. If it would kill stock, there certainly would have been some dead. The bees became so troublesome that we moved some of them. This spring it is not so bad.

Fair Oaks, Ind., March 22.

HENRY ROORDA.

## BIND YOUR JOURNALS.

Mr. Todd's account of his unsuccessful hunt through the bee-books for something on flour candy, and the editor's reference to old volumes of GLEANINGS, lead me to describe my practice. While there is nothing new in the idea of binding magazines, it is not generally practiced among bee-keepers. I find that the journals stored away in the closet are seldom referred to, while those nicely bound and placed on the shelves are in frequent demand. One year's issue of GLEANINGS makes a large book. We get it bound in serviceable half-leather for one dollar, and a single volume is worth two or three ordinary books on bee culture for reference. Eight or ten volumes of this kind will make an encyclopedia of bee lore that can not be equaled by all the well-known bee-books combined; and one has little idea of the frequency with which it will be used. In almost every issue there are valuable articles, not of present interest, that are lost entirely unless preserved in some permanent manner. The first cost of the journal is one dollar; and by adding another dollar to the cost we can increase the practical value not only twice over but many times as the value increases with the years.

Atlantic, Iowa.

FRANK C. PELLET.

## TO KEEP GRASS DOWNS AROUND THE ENTRANCES.

The problem of keeping weeds and grass from growing in front of hives seems to be a vexing one with many bee-keepers. It really is very simple. One way is to use boiling water; but it takes a lot of it, and the hot steam in front of the hives fills the bees with the agony of helpless despair. A solution of arsenite of soda also would be effective; but poison, especially a mineral poison, should never be used for any purpose where something else is available.

Lay a strip of tarred building paper, such as has been recommended for wrapping around hives for winter protection, along on the ground in front of the hives, extending in under the alighting-boards, and weight the paper down with stones, bricks, sticks of firewood, or any other handy material. This to be done in the growing season of the weeds and grass, including two or three days of sunshiny weather. The paper can then be shifted along to some other place, and the operation repeated until the whole yard has been attended to. How many treatments might be necessary during a season I do not know, but certainly not very many.

Carthage, Mo.

B. C. AUTEN.

## MORE PROOF THAT BEES MOVE EGGS.

On page 780, Dec. 15, last year, Mr. Samuel Simmonds doubts the ability of bees to move eggs. About the year 1882, one of my strong colonies lost a virgin queen; so a little later I cut out a square inch of comb with eggs to give to this colony. I laid this piece of comb near the entrance, intending to put it in the hive; but just then I had to go to dinner. After dinner I found all of the eggs gone out of this piece of comb. I did not see this colony again for more than a week, and then I looked to see if they had a queen, and I found two large queen-cells that were capped over. I was Italianizing at that time, and the eggs which I had given this black colony were from my first Italian bees. The resulting queen was an Italian. If Mr. Simmonds will lay a piece of comb containing eggs against the entrance of a hive that has lost a virgin queen he will find that he can raise nice queens.

I intend to prepare a colony for queen-rearing, provide artificial cell-cups, etc., and, when the bees feel the need of a queen, place a frame of eggs that are one or two days old, flat on the bottom-board, and see if the bees won't do their own grafting. This frame must not be suspended or the bees will build cells on it.

Carrollton, Ohio.

C. V. KINTNER.

## WILL SULPHITE PAPER-MILLS INJURE BEES?

A sulphite paper-mill is being built here. Some say that the sulphur fumes will kill my bees. If it will kill them, tell me how far away I must move to be safe. I live 1½ miles from the mills now.

Ladysmith, Wis.

JOHN ARMSTRONG.

[We have had no personal experience; but if you are 1½ miles away from the mills it would seem very unlikely that you would notice any great loss. If others, who are in a position to know, have reason to believe otherwise, we should be glad to hear from them.—Ed.]

## Our Homes

By A. I. ROOT

And out of the ground made the Lord God to grow every tree that is pleasant to the sight, and good for food; the tree of life also in the midst of the garden, and the tree of knowledge of good and evil.—GENESIS, 2:9.

And the Lord said unto Moses, Make thee a fiery serpent, and set it upon a pole; and it shall come to pass, that every one that is bitten, when he looketh upon it, shall live.—NUMBERS, 21:8.

Come unto me, all ye that labor and are heavy laden, and I will give you rest.

Take my yoke upon you, and learn of me; for I am meek and lowly in heart; and ye shall find rest unto your souls.

For my yoke is easy, and my burden is light.—MATT. 11:28, 29, 30.

If you have not recently read the second and third chapters of Genesis I should like to ask you to turn to them. Please read with care especially the third chapter. If, like myself, you are pretty well along in years, I think you will admit this is a wonderful story of the birth and childhood of the human race. No matter what your belief is, I think you will agree with me that it touches humanity as nothing else has ever touched our origin since the world began. When I was less than a dozen years old I overheard an ungodly man censuring God for having placed that "tree of life" in the very center of that garden, and then forbidding Adam to touch it. For over 50 years I have in my mind considered this thing: Why *did* our heavenly Father place there that tree "of the knowledge of good and evil," and then forbid Adam to go near it? Does not the story suggest humanity's struggle even now?

A little child, the baby, that is just learning to reach out its little fingers to explore things, notes how the mother says, "Burny, burn!" as it comes near the hot stove. Is it not so more or less, clear down to old age? A man, like a locomotive, would be useless unless strong steel rails kept him in the "straight and narrow path."

Adam deliberately broke God's holy law almost as soon as the law was laid down, and in so doing set an example of disobedience for the whole human race, and put the stamp of rebellion against proper authority on all his posterity, clear down to the present time. When Moses, by God's command, undertook to lead the people out of slavery and bondage into the promised land he found the "old Adam" rooted and grounded in the whole gang. They were a set of grumbling rebels; and one of their grievances was, they couldn't have the "flesh" and "onions and garlic" that they had when in captivity. The Bible doesn't really say so, but I shouldn't wonder if they complained because they couldn't have "three square meals a day;" but I expect to touch on this later on. Their "mutiny" finally got to be so great that God sent "fiery serpents" to discipline them. Right here

we have one of the first examples of God's tender mercy and love for his rebellious children. In order to extend free pardon *instantly* to every penitent child he directed Moses to make and carry aloft the "brazen serpent" that every one who really was sorry for his rebellion might "look and live," as we have it in that beautiful hymn.

Well, friends, although you may not have thought of it, that brazen serpent is *still* up before us, and, "glory to God," we may even yet look and *live*.

Away down along the ages came one who was commissioned to issue an "emancipation proclamation," and who has the power and authority to "make good" his wonderful and precious invitation. Since the world began, just one, and *only* one, has been permitted to use these wonderful words, "Come unto me, all ye that labor and are heavy laden, and I will give you rest. Take my yoke upon you, and learn of me, for I am meek and lowly in heart; and ye shall find rest unto your souls. For my yoke is easy, and my burden is light."

Some of you may now object to the way I am going to use this beautiful and gracious text; but I feel sure the Holy Spirit is back of me when I try to tell you of the wonderful way in which many of you, at least, may find *emancipation* from your troubles.

The "yoke" Jesus mentions is the yoke of *self-sacrifice*. You must give up thinking of *self* so much. If you want your burdens to be *lighter* you must give up and forget selfish appetites and selfish notions. You must commence following in the footsteps of him who "pleased not himself."

With this long preface I am now almost ready for my especial message to *your own self*. Now, this is not for somebody else, mind you; it is for the one whose eyes rest on this printed page. The "revelation" came to me in this way:

I have just one brother living, who has been for about 20 years in Arizona. He has just done a most sensible thing in deciding to come down here to Florida and make us a visit. If you, my friend, have neglected for many years to visit your brothers and sisters, get right at it (before God takes you away) and see how much good you may do by so doing. Well, this brother is no taller than I am, and yet he weighs about 180 lbs., while I have seldom gone beyond 130. Several years ago he was in poor health, and had distressing night sweats. About three years ago he discovered that when he ate very light suppers this trouble was better; and finally, when he ate nothing at all after his noonday dinner, the sweats entirely disappeared. I believe that, about the same time, he took up having a sponge bath with cold water every morning. Isn't it funny that he, without knowing it, has adopted Terry, so far, almost to a dot—"a cold bath every morning, and two meals a day"? Simple, isn't it? Well, Mrs. Root has trouble about sleeping, more or less, and she tried "no supper." Very soon she decided she felt certainly as well, and perhaps a lit-

tle better, so the supper was prepared for me alone. Please excuse me here for taking a little space to say that for years I have been most of the time clear used up before every one of the three meals, and, most of all, when it comes "supper time" toward the close of the day. Mrs. Root has for years recognized that, unless I had some good nourishing food for supper, and a good sleep *after* supper (as well as before dinner), I could never hold out to attend to my letters and reading my periodicals during the evening. "Jess" (my brother) assured me several times, that, after just a few days, I would get all over feeling faint, and get through my evening's work *all the better*; but when, for some reason, my supper had been delayed, I had felt so faint and exhausted I could not think it possible. It is true, I had often read what Terry, the good friends at Battle Creek, Mich., Upton Sinclair, and others have said about two meals a day; but I could not scrape up faith to believe such a thing was possible for *me*. Well, Mrs. Root protests about my "rushing into print" before I have tried it longer; but I really feel as if I couldn't wait, without telling you I have now tried it several days; and, although it takes a little "self-denial" (about 5 o'clock every day) I feel very much better in every way without any food after our noonday meal. May God be praised for the "emancipation," not only for myself, but for the "dear wife" who has been tied down to the *slavery* (yes, that is the right word) of "getting supper" for a nervous used-up husband for almost *fifty years*. Through all her busy life she has objected to letting any thing or anybody "go hungry," and even now she worries some for fear I shall "go hungry" and not mention it because of making her trouble. Yes, I do sometimes feel a little hungry when I go to bed (about 10 P.M.), but in the morning I never feel hungry the least bit; in fact, I feel so *exceedingly* well that several times they had trouble in hunting me up (out among the chickens), and getting me to "come to breakfast."

Well, now, suppose you figure up how *many* tired women there are in this world of ours who would gladly be "emancipated," like Mrs. Root, from the slavery of supper-getting. It *may* prove a sort of "yoke" to some of us; but, O my friend and brother! you *will* find, if you go about it in the right spirit, that "my yoke is easy and my burden is light."

If Terry and I succeed in proving that suppers are superfluous (or worse), what shall we say of the evening socials and banquets? Who is the unwilling "slave" that provides all these expensive foods, and afterward washes and wipes the *wagonloads* of dishes? Is there a Moses coming *some time* or *somewhere* in the future to deliver us from the lash of the cruel driver and bring us into the "promised land," even a land flowing with milk and honey?

My brother has been, most of his life, proprietor of a drugstore. His son is a prominent physician with a good practice; but

when he had stubborn night sweats, did he take the remedy from the great array on the shelves of his drugstore? I tell you, nay; he took a cold bath every morning, and ate nothing after the noonday meal.

Terry suggests that two meals a day gives the digestive apparatus a chance to rest up a little—a sort of "vacation." In my case I might almost say it has been the first real *vacation* in thirty or forty years, for I have had three good meals a day almost all my life. Omitting supper is a little different from the "no breakfast" plan; but I think it rather better. When you are ready to sleep, the stomach and bowels are or should be practically empty and at rest; and after you have had a big drink of pure water, when you first get up (*a la* Terry), your clean and washed-out system is ready to do good work with the breakfast. In fact, we might almost say there has been a sort of "cleaning house" and getting rid of all rubbish.

Mrs. Root suggests that, while no supper may be all right for grown people, especially elderly people like ourselves, it would hardly do for children and youth. This may be true. You know the "chicken books" tell us to feed the very young ones every two or three hours, etc. Well, our boy Huber, when at college, of his own accord got on to the no-breakfast plan and kept it up for years, and declared that, by so doing, he got on with his studies better. When in poor health he urged me to try it; but I declared all the time I was sure it would never answer for *me*. Perhaps some of you ask, "How about my apples" (the "best medicine in the world," you know)? Well, I didn't have my apples last night, and I feel so well this morning I think I will take my fruit hereafter at noon or shortly after dinner.

God told Adam (and Eve) not to touch the forbidden fruit, but their love for new things, and their low carnal appetites prompted them to listen to the serpent, and they fell as a consequence of disobedience. God is, in like manner, trying to tell us (if we would but listen) to beware about letting our love for "good things" prompt us to make a bad use of them. Some of us have already acquired unnatural and perverted appetites; but, may the Lord be praised, there is help even for such. "Take my yoke upon you," and you will *surely* find "my yoke is easy, and my burden is light."

---

#### HOME-MADE CRUSHED WHEAT.

*Mr. A. J. Root*:—I have just been reading what you say in GLEANINGS, Feb. 15th, about parched wheat for breakfast food. We have used it for several years, and I should like to tell you how we prepare it. We get two bushels of wheat in the fall, when it is first thrashed, and take it to the gristmill and have it run through the smutter so it is cleaned the same as they clean it before they grind it for flour. Then when we prepare it we take four or five quarts, or as much as we wish to grind at once, and wash it in two or three waters, and then put it in deep tins. Have the wheat about two inches deep in the tins, and put it in a warm (not too hot) oven and let it dry. Heating it when it is wet cooks it and roasts

it just enough to give it a good flavor; then we grind it in a hand mill and cook it in a double boiler the same as you would cook oatmeal. It is better than any food you can buy, besides being so much cheaper. I have tried to get my neighbors to use it. They all like it better than any thing else of the kind. Some have used it for awhile, but do not follow it up, because it is so much easier to buy something already prepared. This wheat prepared in this way is too hard to eat without cooking. I should like to have something of the kind I could eat dry; and one object in writing this letter is to ask you to have your people manufacture a machine (to use by hand) to crush wheat like the Pettijohn breakfast food. A pair of smooth foundation-rollers with a hopper on top to hold the wheat and let it run down on the rollers would do the work. The wheat could be soaked so it would crush easily, and dry after it has been run through the mill. If you would get up such a mill you could sell hundreds of them. It always seemed foolish to me for farmers to sell wheat for two cents a pound and then buy it back at ten to fifteen.

I am what you might call an old-timer. I started in the bee business about the time you did; read your writings in the *American Bee Journal* before you started GLEANINGS, and then took that when you first started it, and have taken it much of the time since. I got one of the first extractors you sent out, and I have it yet, but do not use it. I sold you quite a lot of bees by the pound one year in the 70's, and some queens too I think. I contemplate going down to Florida next fall and buy little place, and go every winter as you do. This winter is pretty hard here in Northern Michigan. The snow is over two feet deep, and keeps blowing in the roads so the track is built up three to four feet high.

Free soil, Mich., Feb. 23.

L. D. ALLEN.

I heartily agree with friend Allen, and find scorched ground or crushed wheat more wholesome and more delicious than any breakfast food or cereal on the market. After the wheat grains are steamed or boiled a little, only a little force is required to crush them, so they will be about the same thing as the Pettijohn rolled wheat in the market. Will our folks in Medina let us know how cheaply such a pair of metal rolls can be gotten up?

## High-pressure Gardening

By A. I. Rood

### HIGH-PRESSURE GARDENING, ETC., IN FLORIDA IN MARCH.

With the good prices during the past winter, celery has been the great money-making crop, and, indeed, I might say during the past two winters. The celery industry has been crowding more and more into this part of the State, for two reasons—first, the frosts that we have are lighter because we are so far south, and also because of our nearness to the warm waters of the Gulf; secondly, because of the wonderful flow of artesian water in almost every part of Manatee County. Now, when I tell you what is being done here do not imagine every one can do it. Almost all the time I get letters asking if the writer can come here and make a living; and quite a few ask if it is *true* that a man can *get rich* on ten acres, etc. Any one of fair ability should be able to make a living here; and there are a few who really do get to be fairly well off on ten acres or less. My neighbor Rood is, or perhaps was,

an educated lawyer; but he likes gardening and bees so well he has given up his office in town and become a farmer. Well, *Mr. Rood* seems to make every thing pay that he touches. When he got the celery fever a year ago I cautioned him about dropping (or at least partly) his strawberry and lettuce that were paying so well, and venturing on something he had never tried. But this is what he did: He went all over this region, used his eyes and ears, and asked questions; read the books and papers, and finally made a success the very first time trying. He has *promised* to give GLEANINGS some figures in regard to what he has done and what it cost; but he is such an exceedingly busy man I fear he won't get around to it. On his best ground the crop sold for something like at the rate of \$1350 per acre.

A hive of bees on the scales gathered last Sunday, March 20, 9¼ lbs. of orange-blossom honey, and this one hive has stored already over 100 lbs. of this beautiful white honey, almost if not quite equal in looks and taste to any honey anywhere. Now, if I should give the above, and nothing more, very likely a great lot of you would "swarm" down here with your bees. The truth is, this is one of his best colonies, built up three stories high. Another truth is, this is almost the first good flow of orange honey for about three years, and the yield is probably confined mostly to localities below the dangerous frost-line.

Even in this county you see deserted orange-groves, gardens, etc., where a lot of money has at some time been expended and then given up. A few days ago I said to Mr. Rood:

"Why doesn't this man go around among his neighbors and see *how* they do things instead of trying to farm and grow the same crops he did up north?"

He replied: "Well, I declare, I don't know. He just stays right here at home, and doesn't go anywhere or see any thing. His land is just about as good as mine, but he hasn't yet even ditched it to get the water off."

I have spoken several times of our mulberries. Two years ago they were little trees perhaps a yard high. Now they are great spreading trees as large as apple-trees in the North, and are *loaded* with great luscious fruit. After breakfast and after dinner I devour them by the quart. They are so dead ripe that when a little breeze comes, they drop all over the ground; but there are more of them than 25 hungry Leghorn hens can take care of. They are so large you would say a common hen could never swallow one; but they manage to "make it," probably because they have practiced on oat-stalks 15 inches long. When a neighbor calls we invite him out to see the mulberries; and it's just fun to see each one utter exclamations of surprise at their size, abundance, and beauty, and, still more, when they taste one. We have now only six trees, but we are planting them in each one of our eight poultry-yards. If you want cuttings or

trees, write to Reasoner Brothers' Nursery, Oneco, Fla.

The first shipments of lettuce brought as good or better prices than heretofore; but toward spring there seemed to be a universal complaint about heading up properly. On this account neighbor Rood's lettuce-field has given my nearly 300 chickens (old and young) all the lettuce they could consume for about two months past. We wheel over to the chickens all that isn't fit for market.

#### FERTILIZING TRUCK LANDS IN FLORIDA.

On p. 240, April 1, are some statements in regard to the cost of fertilizing our Florida lands that may give a wrong impression. I have just been looking at some potatoes on neighbor Rood's land that surpass anything I ever saw in Ohio or Michigan either. When asked how much fertilizer he applied per acre he answered something like this: "Mr. Root, I did not put any fertilizer at all on these potatoes; but I did give the ground a very heavy application when in celery, just before these potatoes. Let me explain. As I considered this one of the poorest spots on my place (and *new ground*), I gave it the heaviest application I have ever made on *any* piece of ground. I suppose we put on something like *four tons* to the acre (where you see these best potatoes) of a fertilizer costing \$40.00 per ton. The celery crop alone sold for over \$800 per acre."

These potatoes were larger foliage, heavier stalks, and better color than I think I ever saw before. Let me explain, that down here there are no Colorado beetles, no *flea* beetles, and no insects of any kind to puncture and perforate and disfigure the handsome potato-plant, for it *is* handsome where permitted to grow free and natural. As they were just coming into bloom, no one can tell as yet what the crop will be; but Mr. Rood dug into a hill and found fair-sized potatoes as clean and smooth as new-laid eggs. Notwithstanding that potatoes may be grown here almost all the year round, nearly everybody uses potatoes from the North. Other crops pay so much better, we can't afford to grow our own potatoes, even if poor ones shipped in *do cost fifty cents a peck*. Our home-grown ones are equal in quality to any I ever tasted in Ohio, Michigan, or Bermuda.

## Poultry Department

By A. I. Root

#### POULTRY SECRETS, ETC.

A subscriber sends us the following advertisement, and asks us to investigate:

**SURE DEATH TO CHICKEN LICE AND MITES GUARANTEED AT SMALL COST.**

We have discovered a cheap and absolutely sure method of thoroughly exterminating chicken lice and mites from poultry-houses. This method has been thoroughly tested with uniform success, and we now offer to make it known for one dollar.

Remember, by our method chicken lice and mites will be entirely destroyed—eradicated—in a few hours at slight cost if our very simple instructions are followed. We are so sure of this, that, in the event of failure to destroy the vermin completely, we will promptly return the money received.

Only \$1.00 for this knowledge, which will enable you to get your poultry-houses free from hen lice and mites if you should be so unfortunate as to have either of these pests upon your premises. Bid yourself of them by sending \$1.00 to

CLOVER HILL FARM, Little Silver, N. J.

A dollar should pay for a good-sized book covering the *whole subject* of chicken lice and mites; but as I seem to be in the "business" I sent the dollar. In due time I received directions (that might be printed on a postal card) for fumigating the poultry-house with hydro-cyanic-acid gas, a method that has been in use for years for killing all insect life in greenhouses. It has been described again and again in our agricultural press, and, so far as I recollect, Mr. Lovett's directions are almost word for word like that of a government bulletin sent out a few years ago. It is also used under a tent for killing insects on orange and other trees. All Mr. Lovett has invented or discovered is using it for *poultry-houses* instead of greenhouses. Of course, the chickens must all be driven out; but will old poultrymen please tell me how much would be gained by cleansing the *house* if you let a flock of infested fowls come right in, people all the cracks and crevices once more just as soon as this volatile gas is out of the way? Zeno-leum, carbonoleum, and all lice-killers sold penetrate the wood and keep out vermin for months or years afterward. But *that* isn't all. Before you can use this "dollar secret" you must make all your poultry-buildings absolutely *air-tight*. How much do you suppose it would cost *me* to make my six Florida (wire netting) houses so they would hold this gas made from sulphuric acid and cyanide of potassium?

This whole thing is a pretty fair sample of the average "poultry secrets" advertised for a dollar or more. I hardly believe a poultryman with the reputation Mr. Lovett has would be led to go into such a thing were it not that so many others have been "setting the pace."

One thing more: The Cyphers people and other dealers have for years advertised sulphur candles for fumigating and destroying all insect life in poultry-houses. Why should Lovett or any one else want to use this very dangerous and expensive gas, comparatively, when cheap common sulphur does the business perfectly? Is it not about time for the Department at Washington to forbid the use of the mails to such chaps?

#### BACK TO MEDINA, OHIO.

We are now planning to leave Bradentown, Fla., for Medina, on April 19. Will our many kind friends take notice, and direct all missives for myself to Ohio, after they see this? A. I. R.

## EDITORIAL

By E. R. ROOT

THE Ohio foul-brood bill is now on the calendar for vote in the senate. Write your senator at once, urging his support.

*Later.*—The bill has now passed both houses.

D. M. MACDONALD makes a strong plea in this issue, page 296, for the much condemned black bees. The article is ably written and very fair. It is worthy of careful reading.

THE chilly weather of the last two weeks, that seems to be almost universal over the Northern States, will doubtless cause a great deal of chilled brood. Do not jump at the conclusion that you have foul brood.

### OLD OR NEW FOUNDATION.

ATTENTION is called to a Straw of Dr. Miller's in this issue, on the relative merits of fresh and old foundation in sections. The doctor takes the ground, it will be noticed, that the bees will work on the one as well as the other. We shall be glad to get the experience of others who have tried it.

### PARCELS POST.

WE have not said much lately about parcels post. It is a strategic time now for bee-keepers to write their Senators and Representatives, urging their support of this needed legislation. The following, from the *Ohio Farmer*, shows the benefits that would accrue from a parcels-post system. It will be especially valuable to bee-keepers:

The first postal need of to-day is a rural service on a paying basis with the elimination of the postal deficit. A cheap general parcels post will quickly follow. The posting of one five-cent packet each week by the average farmer to and from the town where he sells his produce and buys his supplies will insure a postal income of \$10.00 a week per average route, or \$20,000,000 a year for the entire service. The wants of the hundred families on the average route surely warrant the expectation of a business of at least one ten-cent packet a week to and from the farmer's market and his home, with a resulting rural income of over \$40,000,000. Even this business implies a constant load by the carrier of less than 18 packets weighing, possibly, 300 lbs.

The establishment of a daily service of two vehicles going in opposite directions over the same course will soon be needed; and cutting down the haul of all matter one-half will at once quadruple the capacity and the efficiency of the service. We are assured by the highest authority that there are several routes where this proposed service will be a

success from the start. Its trial will prove a wonderful object-lesson as to the benefit of good roads and of machinery adapted thereto. We pray the financial and personal aid of all the friends of postal progress, and especially the aid of the press, in arousing the public opinion needed to secure the needed legislation. J. L. COWLES,  
*Secretary-Treasurer of the Postal Progress League,*  
361 Broadway, New York.

No one is fighting the parcels-post system except the small country storekeeper and the express companies. It has been a success for many years in Europe, and we should have had it long before this had it not been for the Cannons and Aldriches in Congress.

*Later.*—See Colorado department.

### "BEE-KEEPERS' LEGAL RIGHTS."

THE new edition of "Bee-keepers' Legal Rights," by the National Bee-keepers' Association, has just been issued from the press. Like the old edition it contains copies of laws and court decisions relating to bee culture. Besides that, it has a long array of testimony showing the valuable service performed by the bees in pollinating fruit-trees. The last few pages are devoted to copies of the various foul-brood laws as they stand on the statute books in the several States to-day.

Every member of the National will doubtless have a copy, and every one who has not would find this book, "Legal Rights of Bee-keepers," worth the dollar membership fee alone. He should be familiar with its contents, so that when trouble arises he can meet the enemy with hard cold facts, both in and out of the court-room. This is a case where knowledge is power.

See what General Manager France says about it in another column. Of course, it is understood that no one can get a copy unless he is a member or is enrolled as such, as the book is not for sale.

### NON-SWARMING BROOD-CHAMBERS.

IN this issue, pages 295 and 299, we show illustrations of two different styles of anti-swarming devices. As we understand it, these have not been tried very extensively. The basic principle seems to rest in having a large clustering-space either beneath or in front of the brood-chamber, but such clustering-space so arranged that no comb can be built in it. The idea seems to be an adaptation of the Aspinwall principle of furnishing a clustering-space; but instead of placing that space *between the frames*, as does Mr. Aspinwall, these other people would place it in front of or under the brood-chamber.

If we are not mistaken we had a talk with Mr. Aspinwall regarding some plan of this kind, and he told us he had been over this ground, and that the clustering-space had to be disposed between the combs to be effective.

We present the idea in two different forms, because it may involve a principle having some merit; but until it can be tested, everybody should go slow, for we have been fooled so many times about this swarming proposition that, when a new thing looks good, like this, we should remember past experiences.

#### PROSPECTS FOR THE SEASON.

A large number of reports have come in since our last issue, and only about one in four is unfavorable; that is, three out of four report good wintering, good prospects for the season, etc. As is always the case, there are sometimes conflicting reports from localities close together. This is often due to difference in care used; but this year it is quite probable that the difference in the quality of the stores has a great bearing on the matter. As we have already stated, at one of our outyards nothing but honey-dew was gathered, while two miles away a fair crop of light honey was secured. The contrast was quite marked this spring. At the yard where so much honey-dew had been gathered, many of the colonies showed symptoms of dysentery, and, all together, they were in much poorer condition than at the other yards. Sugar was fed in both places; but in spite of this the honey-dew still in the combs in the late fall made trouble.

The light snow which has fallen over a large portion of the North, instead of hurting the prospects has served to put the clover in much better condition than it was before. Snow in April is almost always good for clover. Fruit has been injured to some extent by the frosts; but the bee-keeper, unless he is a fruit-grower also, can console himself with the thought that, when fruit is scarce, honey is apt to be higher in price.

#### ARE BEES KILLED WHEN FRUIT-TREES ARE SPRAYED WHILE IN BLOOM?

A YEAR ago, as will be seen by page 514 of our last year's volume, we published a letter from O. B. Metcalfe, of Metcalfe & Parks, Mesilla Park, N. M., showing how five of their yards had been almost entirely ruined because neighboring fruit-growers sprayed their trees while in bloom; of how not only the bees died by the thousands, but the brood also. The other yards remote from this spraying did not suffer any injury. We have had other proof from time to time of how this ignorant spraying at the wrong time ruins the bee-keeper's prospects for honey, if it does not entirely clean out all his bees. The following letter gives further evidence along this line:

We are having bad luck with our bees. One of our neighbors sprayed his fruit-trees while in full

bloom, and it ruined us. The bees are still dying. That was four days ago. We have had a big rain since, which seemed to help somewhat. Does Paris green usually kill the brood? The bees carried out larvae in all stages. Does it kill or injure the queen?

I wonder if there could not be a law passed in Indiana in regard to spraying fruit-trees while they are in bloom.

Lebanon, Ind.

J. W. SWAILS.

We have not thought it necessary heretofore to give any special prominence to the fact that bees are killed if trees are sprayed while in bloom; but as the fact was doubted by one or two of our very good bee-keeping friends, we shall be glad to hear from others who have suffered. No damage, of course, occurs when the non-poisonous mixtures like lime and sulphur washes and the kerosene emulsions are used; but, as any intelligent fruit-man knows, these are insufficient to kill all the pests.

During the years past we have had a good many hundred reports where bee-keepers have written in and asked why their brood was dying, supposing it had died from foul brood; but investigation showed that in many cases, at least, this brood was poisoned, and that as soon as the spraying season was over it ceased to die.

In answer to Mr. Swails we may state that there is no law against spraying fruit-trees while in bloom, in Indiana. There is no such law in force except in the State of New York, in Ontario, Canada, and possibly Michigan. Conditions became so bad in York State that the bee-keepers of that commonwealth put in a strong plea to their Legislature and secured the law.

#### PREVENTION OF GRANULATION OF COMB HONEY BY KEEPING IT IN A WARM ROOM.

ON page 134 we spoke of the fact that a carload or two of our western alfalfa honey showed a tendency to granulate, and that we expected to arrest granulation by storing it in a warm room subject to a temperature of between 80 and 90 degrees Fahr. Some experiments that we had conducted a year or so before on a small scale led us to believe that we could not only arrest granulation, but that we could actually reduce it. The temperature of the room in that case was slightly above 100, and some cakes of honey that was granulated solid were actually brought back to a liquid condition; but we found that this high temperature had a tendency to make the combs sag in the sections.

This winter we put a carload and a half of comb honey in a large room, into which we had put extra steam radiation, maintaining a temperature nights and Sundays continuously of between 75 and 90 degrees. While we held granulation in check, we noticed that a good many of the combs had sagged to an extent that it spoiled the chance of marketing them. Nearly all the honey that has been held in this high temperature has suffered slightly in flavor. The average consumer would not notice it,

but an expert can readily detect a comb honey that has been kept in a hot room for three months from that which has been, say, a month off the hive. With this slight impairment of flavor, and very slight it is, there is a barely perceptible darkening of the honey itself. Taking it all in all, the experiment conducted on a large scale is somewhat disappointing. It is almost a case of between the devil and the deep sea. A comb honey that is granulated to a greater or less extent is slow selling, and at very moderate prices. If we stop the granulation by the hot-room plan, and prevent other honey from starting, we run the chance of darkening and impairing slightly its flavor.

#### WHAT TO DO WITH CANDIED COMB HONEY.

We have been conducting some other experiments in liquefying candied comb honey, running it through a capping-melter machine, and, by the way, one of these machines is just the thing for this purpose. The combs are cut out from the sections and dropped into the capping-melters. The candied honey and the wax melts up together. The combined product flows over into a receptacle. A pipe connecting with the bottom draws off the free honey while the wax flows over the top. The thing goes on automatically about as fast as a man can cut the combs.

Experience shows that if candied comb honey can be sold for 10 cents to a certain cheap trade, that it is better to sell it that way than attempt to melt it up; but if it won't bring 10 cts. then one can make nearly that figure by selling the honey in the extracted form, and the wax, when melted up, at a combined figure that will net nearly 10 cts. Strangely enough, the honey that runs through the capping-melters in this way is of good color and body. The body, however, is a little too good, that is to say, the honey is very thick and waxy, and probably would not candy readily; but there is a very slight impairment in the flavor—so slight that none but an expert would notice it; but when this erstwhile candied honey is run through the capping-melter in connection with the wax, and put alongside of honey that has been taken from the hive and not heated, the consumer would notice a slight difference in favor of the latter. If they were kept separate he doubtless would not see or taste the difference.

#### BABY NUCLEI FOR THE REARING OF QUEENS; WHY SOME OF THE PRATT OR SWARTHMORE METHODS FAILED.

On page 283, in his regular department, our old correspondent Mr. G. M. Doolittle does not take very much stock in baby nuclei for the rearing of queens. But the form of baby nuclei that he particularly condemns we do not think is now in use. We tried out the Pratt (or Swarthmore) nuclei (the kind he seems to have in mind) one season, and proved that we could fertilize queens on that plan; but as the little clus-

ters of bees were too much inclined to swarm out and cause trouble we finally gave them up. The larger twin nuclei, capable of holding one-half to three-fourths of a pound of bees in both sides have given excellent results. The baby hives are made of  $\frac{3}{8}$ -inch lumber; have a double cover and a telescope that slips down over the whole, reaching two-thirds of the way down to the entrance. The form of the hive is almost cubical; and when there are two clusters of bees (one on each side of a division-board  $\frac{3}{8}$  inch thick), approximating 1000 to 1500 bees in each, experience shows that no cell or virgin is chilled. It is very easy to determine when this takes place. Yellow queens, if they are chilled at any time in the cell or virgin state, are apt to turn dark and look small. The fact that some of the most prolific and best queens we have ever reared have been raised in these large twin baby nuclei goes to show that they are the equal of the larger colony or larger nuclei having the brood scattered over a much larger surface, more exposed to the changes of temperature. A small clustering-space of two or three thousand bees in a cubical or compact double-walled hive will keep as warm as or warmer than a much larger cluster in a long flat brood-chamber having Langstroth frames. By the way, this frame makes a poor nucleus. It is too large and too long. Our large twin nuclei are used only during the months from May to the first of September; that is to say, during the hottest months of the year. Before and after that time our queens are reared in full-sized colonies. Apparently Mr. Doolittle has much cooler nights during the warm months than we have.

There were a good many fancy tricks of the trade that the late Mr. Pratt was able to work successfully that the rest of us who practice queen-rearing on a large scale could not make go. Mr. Pratt was a genius—a wonder in his line. We have seen him perform feats in queen-rearing that others could not accomplish. On a large commercial basis many of his ideas were impractical. In his mild climate he could do many things that were impossible elsewhere. It is not strange, then, that many who tried to follow him failed.

We presume that we have criticised his methods as much as any one; but when we saw him actually do the stunts that he described, we doubted no longer. As most people lack either his special environment or his consummate skill, it is a waste of time and money for them to attempt to follow some of his ideas, at least. For example, his 50 or 100 bee baby nuclei were impracticable in most localities. We could make them work only during the very hottest months of the year. At any time they were liable to swarm out, or worse yet, be robbed out. Moreover, they had to be supplied with fresh bees every so often. We experience none of these troubles with our much larger double-walled twin nucleus hives.

## Stray Straws

By DR. C. C. MILLER, Marengo, Ill.

SIX SPACES of bees on a frosty morning the first of May is better than more or less, says Doolittle, p. 211, and, as usual, I suspect he's right. I don't have many as good as that ever, and can easily reduce any that exceed it (and I always do), but the laggards are what beat me.

J. L. BYER wants winter entrances not less than 10 or 12 inches by  $\frac{1}{2}$ , and backs up the idea with pretty stiff arguments.—*Canadian Bee Journal*, 72. [Mr. Byer may be right. We noticed that some of our colonies last winter that had, by mistake, larger entrances than usual were not only in fine condition, but the combs were dry and sweet. There is a nice golden mean somewhere, and we shall invite a discussion of the subject next fall.—ED.]

LOUIS SCHOLL, you want to know, p. 246, when I'm going to try some bulk comb honey. I've just reread your array of troubles in trying to produce section honey, p. 39, and it does look as if I'm a goose to go through all that and then get no more for sections than bulk. But why didn't you tell me all that before my bees got so in the habit of storing in sections that I don't have a title of the troubles you catalog? Still, maybe I'd better. Say! do you *know* of any market in the North where I can sell bulk for the same as I do sections?

F. GREINER, p. 181, agrees with the editor, that "we shall sooner or later be compelled to give up the use of sections on account of the scarcity of suitable timber to make them." Well, we can go back to four-piece sections, same as we first used, and almost any timber will do for them. [It will be at least ten years, and probably more, before we shall have to give up sections. In the mean time, it is our opinion that some form of carton to hold cut comb honey will gradually take their place. Basswood is a rapid grower, and it is safe to say that a large proportion of the sections of to-day are made from lumber not over ten or fifteen years old. A basswood in front of the editor's home is 11 inches in diameter, and only about eighteen years old. Another tree the same age is 9 inches. As a general thing, basswoods will grow more rapidly in a forest than out in the open, for they seem to like shade in their earlier years.—ED.]

FIVE or six weeks' time is given as the lease of life of a worker in the busy season. That was the belief fifty years ago. At that time, and for years afterward, it was easier than now to test the matter, and thousands had the opportunity to test it, for pure blacks were common then and scarce now; and when an Italian queen is introduced into a black colony it is easy to tell when the

last black disappears. The many who observed agreed that in the busy season about six weeks is the limit of life, and that belief has gone unchallenged through all these years until now, when we are told by G. A. Wright, page 270, that with his hybrids the limit was 27 days. It is easier to believe that Mr. Wright's bees are exceptionally short-lived, or that some mistake has been made in observation—for some hybrids can not be distinguished from Italians—than to believe that every one heretofore has made the stupendous mistake of making the time 55 per cent longer than it should be. It must be remembered, however, that if six weeks is the life of the last bee that disappears, the average must be at least a little less than that, for it is not likely that all should die at exactly the same age. [The trouble with our friend Wright was that he was basing his conclusions on practically a single experiment. With hybrid bees he would have had no means of proving absolutely the correctness of his conclusion; for many hybrids will show up like nicely marked Italians.—ED.]

"FOUNDATION should be fresh. If it was put in sections the previous year, the only thing is to pull it out and melt it over." That's what one says. Another says, "Foundation doesn't spoil with keeping; it's just as good when five years old as when fresh from the mill." How can it be that such opposite views are held? Can both be right? In a way, yes. I've had experience both ways. Every year I aim to have ready in advance enough sections filled to answer for the biggest kind of crop. So, of course, most years a few thousand will be left over, and I think I've had some sections that had been filled four or five years. I couldn't notice but that the bees began on the foundation just as promptly as if it was fresh. Of course, I think there must be some difference—the fresher the better. But the difference is very little. If not put in sections, but kept packed in sheets, it's hard to say how many years it would keep. On the other hand, I've had sections of the previous year's filling that the bees would none of. Such sections would be left entirely empty while the rest of the super would be filled. They had been left on the hive at a time when no honey was coming in, and the bees had given them a sort of polishing, perhaps a thin coat of propolis. The only thing to do is to melt up such foundation. The moral is: Don't worry about foundation being old; but never allow sections in the care of the bees when they can do nothing with them but spoil them. If there's a dearth of considerable duration between two honey-flows, take off the sections at the close of the first flow, and then put them on again at the beginning of the next flow. But early in the season, before the first flow, no harm comes to the sections from being on; it's in the fall that the mischief is done, mostly by being too slow about taking off all supers promptly at the close of the flow.

## Notes from Canada

By R. F. HOLTERMANN

So Dr. Miller has twice had "the last word" upon the rights of bee-keepers to a location. Seeing that he has a good many sound arguments to reply to, his opportunities have not exceeded his needs.

### PREVENT ROBBERING.

To Jacob Alpaugh, inspector of apiaries, credit is due for the idea of warning, by letter, the bee-keepers in foul-brood districts against allowing bees to rob out hives in which colonies perished during the winter or early spring. [This is very important.—Ed.]

### THE WEATHER.

It is scarcely necessary to say that the weather has been very remarkable. During the week beginning April 4 the bees had a royal time on soft maple, willow, etc.; they flew heavily loaded; and whatever the outcome may be, so far they have had a better chance to secure stimulative food than they have had for years.

### CHUNK HONEY.

Wesley Foster, page 209, April 1, condemns the idea of producing chunk honey in Colorado. In Ontario, to encourage the production of comb honey in large frames, cutting this out and putting pieces of comb in vessels, and pouring extracted honey on it, would be a great mistake because of our rapidly granulating northern honey. Think of a customer buying this on faith as partly comb, or think of the dealer trying to show the customer the comb honey submerged in the granulated extracted. I doubt if people have faith enough in one another in Ontario to deal in this way very extensively.

### THICK SYRUP.

On page 206, April 1, the editor refers to thick syrup fed late, stating that "good results" were obtained, etc. Where there are some natural stores, especially if they are of doubtful quality, the later the bees are fed the better, if the syrup is thick. Let the bees consume the inferior stores while they can fly. Then by late feeding are the bees not less likely to start brood-rearing? and will there not be less excitement and waste? I would consider the recapitulation by the editor excellent, only I would dwell a little more strongly on the danger of honey-dew in winter stores. [Your point is a good one. By feeding late we give the bees an opportunity to use up as far as possible their old and undesirable stores, such stores as would not be suitable for a winter food. This may account in part for the good results following our late feeding.

It is also true that early feeding has a tendency to stimulate brood-rearing, especially

if that syrup is thin. The wear and tear on the bees in reducing this syrup to the proper consistency so pulls down their vitality that some of them die even before winter actually comes on. Feeding always has a tendency to force the bees out in flight, and if the weather should be a little chilly many will be lost. Very late feeding with thick syrup in weather too cold for bees to fly can not force them out, and, what is more, the syrup is immediately stored. As a result there is little or no wear and tear on the bees that must necessarily undergo the rigors of winter.—Ed.]

### CONDITION OF BEES.

It is probably a good many years since bees in Ontario have come through the winter as well as they have this season. Colonies wintered in the cellar or packed outside (I have both) are alike in good shape. During the past week, beginning April 4, I went through nearly all the colonies, examining them sufficiently to determine that they had queens and did not lack stores. I found plenty of capped drone brood, but, so far as I can now remember, there did not appear to be much hatching worker brood. Is this because the winter was so very steady, and the bees remained in their packing quietly clustered? [There were plenty of young bees in this locality at this time.—Ed.]

### SEALED COVERS VS. ABSORBENTS.

On page 207, April 1, the editor, in part, states: "We have a suspicion that those who so loudly champion the absorbing-cushion plan of wintering may not have tested side by side the sealed-cover and absorbing-cushion plan." May not conditions have much to do with this question? I have known of cases where prolonged cold, at a time when the hives were not covered by snow, resulted in the entrance being frozen up or practically so by the condensing moisture. When the moisture passes up through the packing there is no danger of this.

Then I "have a suspicion" that these covers are not *sealed* if sealing means that no moisture passes up and is absorbed by the packing. In painted hives I have been surprised to find moisture pass through the  $\frac{3}{8}$ -inch wall and then form a blister between the board and paint. I have, however, a case this spring where a colony wintered well, although, through an oversight, having a hive-cover that was covered on top and the sides with galvanized iron; yet I have not sufficient faith in the method to try the plan. Locality surely has something to do with results; in the extreme northerly apicultural sections, in my estimation sealed covers are risky. [We quite agree with you that conditions have much to do with this question. In localities where the entrance is liable to be sealed with ice, the absorbing plan doubtless would be better.

When we refer to "sealed covers" we mean those that are secured by the ordinary propolis sealing. They may or may not be hermetically tight.—Ed.]

## *Bee-keeping Among The Rockies*

By WESLEY FOSTER, Boulder, Colo.

### CORRUGATED DRIP-BOARDS.

The corrugated drip-boards are away ahead of the wooden drip-sticks. They are more quickly put in a case, and they also make a good cushion when the case is jarred. The drip is absorbed if not too much, and there should not be much in a good case of honey. After unpacking several hundred cases where the corrugated boards were used I can say they look good to last.

### SWARMING IN THE WEST.

Swarming is not as serious a problem in the West as in the East, for two reasons. There may be other reasons, but I will give only these two now: The honey-flow is never so rapid in the alfalfa regions as in the white-clover, basswood, or buckwheat localities of the Eastern States. The bees do not become worked up to such a high tension as where the flow comes on in a very torrent. If there is not a sixty-day flow from alfalfa the surplus is not likely to be very large. The bees take things more calmly, and proceed to enter the supers, many times, without thinking of swarming.

The second factor is the cold nights we have which act as a sort of damper to the warmth of the swarming fever. We often have a few days of cool weather which will frost the notion of swarming. But seasons do come when our bees are as bad as any, but I think they are more rare in the high cool altitudes.

### BEE-KEEPERS AND THE PARCELS POST.

Even the most observing of citizens are slow to see the damper placed on our national progress by the withholding of that great human betterment, the parcels post. That which we do not see as a definite loss does not strike us as real; but even if we do not see what we are missing in prosperity by the lack of this reform, the loss is none the less real. The cost of expressing a gallon of honey from Denver to Kansas City is now about 75 cents. The cost need not be over 25 cents, and that would be three times the fourth-class freight rate.

The parcels post will make the selling of honey by mail order the most profitable way for the wide-awake bee-keeper to sell his honey. The consumers who are now anxious to connect themselves directly with the producer will be able to do so economically under the parcel-post method. Honey and other farm products will pass more directly from the producer to the consumer. This will effect a great national saving that will make us all richer. With the adoption of the parcels post I expect to see honey eaten

much more, and this will tend to give us a better price for a choice article.

These instances show that bee-keepers can not be too well posted on freight rates, classifications, and the proper way to ship honey. If the freight agent in the first case spoken of had been looking out for the best interests of his company's customers he would have told the bee-keeper how to secure the lowest possible rate.

### THE POPULAR CONCEPTION OF HONEY.

One who works with honey, and is thinking of it a great deal, can hardly realize what people in general think of it when they see it in the stores or have it brought to their attention. There is one thing that has very agreeably surprised me, and that is the high regard as a food at which honey is rated. There is that flavor in the thought the word carries which suggests *par excellence* of sweetness. The word is the oldest one in our language for a sweet, and, being in use every day, is well advertised. This idea of quality that adheres to the word "honey" can not be maintained without a correspondingly higher price being asked than for other sweets. One of the very things that make people suspicious of the purity of honey is its cheapness. If honey in the comb or extracted honey in glass and tin could not be bought for less than twenty cents a pound there would be many more people who would have confidence in its purity. What we bee-keepers need to know is that pure maple syrup will bring \$2.50 a gallon; and is not a fine quality of honey worth as much? Maple sugar sells for 30 cents a pound in many stores in Denver now. Honey should come much closer to it in price than it does at present, though it is also true that a very fine quality of comb honey will sell readily at 20 cents per section.

Some of the readers of GLEANINGS no doubt read the article in February *Hamp-ton's Magazine*, "What has become of our Pure-food Law?" by Samuel Hopkins Adams. Mr. Adams stated in the article that the markets of the country teem with honey that is mainly glucose. I wrote to Mr. Adams that I thought the facts must be overdrawn, as I had never seen any honey that I thought contained any glucose, out here in Colorado at least. He replied that he got his information from the reports of the State Food and Dairy Commissioners of Illinois and Minnesota.

Mr. Adams asked if it were not a fact that the low price at which certain low grades of honey are sold did not bear out his contention of adulteration. Now you see when a man like Mr. Adams sees honey advertised for five and six cents a pound, he, not being familiar with the methods of production, thinks pure honey could not be sold for so little, so it must be adulterated. If the low price we bee-keepers are getting for our honey casts the suspicion of adulteration upon it we should have the courage to raise the price enough to instill confidence at least.

## Conversations with Doolittle

At Borodino

### CONDITIONS WHICH INFLUENCE THE DEVELOPMENT OF QUEEN-BEES.

"I reared a few queens last summer, and was infatuated with the work. What are the conditions under which the *best* of queens can be reared?"

"Did you ever go to a colony which was preparing to swarm, Mr. White, and ask the bees how they reared queens so as to bring themselves all the way down, from creation to the present, in such good condition?"

"But, Doolittle, queens can not be reared in the numbers needed for market as the bees rear them for swarming purposes."

"Possibly not, under just the same circumstances, but we can come very near to it. Most of those who advertise queens for sale do the best possible to bring about the conditions needed, I think."

"A few years ago one of our noted men said, 'In a normal colony a queen emerges into an atmosphere of warmth and high humidity, and has accessible an abundance of nutritious and stimulative food.' Would that describe the condition in which queens emerge under the swarming instinct?"

"Yes, and it also describes the condition under which most queens emerge, when reared where an old queen is superseded by the bees during July and August, the time of year that supersedure occurs most often."

"And are queens reared under the supersedure impulse as good as those reared under the swarming impulse?"

"I have not found them inferior."

"Does the Swarthmore plan come under either of these conditions? I read in a paper purporting to tell what Swarthmore said regarding the little colonies in which he had his queens during the time they emerged from their cells, time of mating, and till they were sold or given to his own colonies, where he desired to requeen: He said that twenty-five bees will mate a queen. Fifty will do it better, but more than a small teacupful is a positive disadvantage. When I read that I said I was going to talk this matter over with you; and if you, who have been in the queen business for more than a quarter of a century, endorse this statement, then I was going into the queen-rearing business by putting a big advertisement into each of the bee-papers, splitting up part of my colonies into teacupful lots, when, by the pre-introduction plan, I could get a dollar queen from each teacupful once a week. As each colony would make from twenty-five to fifty such cupfuls for that many nuclei, I could make 500 or more nuclei from the colonies which I put into queen-rearing, and work the rest for honey. In this way I would more than double the results from my apiary each year."

"You remember what you quoted from

one of our noted bee-keepers, one having years of practical experience, about the conditions under which queens emerge in normal colonies. Well, that normal colony condition can not be obtained in any commercial queen-yard, subject to all of the changes of weather in your latitude and mine, with a teacupful of bees of any age; and I have been greatly surprised that some of our bee-papers should lend their influence toward baby nuclei and the pre-introduction of queens to such. I have tried the matter very fully, introducing to my own colonies the queens thus reared, so that I could prove this matter before I sent out any queens that might be a damage to those who purchased them, and the result proved that such queens did not come up nearly to the standard of those which emerge and were mated in nuclei having from three to six full combs, with bees to cover them fully, as has been my way for the past thirty years; so that all of this pre-introduction and twenty-five-to-fifty-*bee* baby-nuclei contraptions have been burned."

"But you did not tell why a normal condition could not exist with a cupful of bees."

"It is barely possible that it might in mid-summer, in a latitude like Florida and Texas, where there are no cool nights (if there be such a place); but with us who are not so favorably located, it is best to be sure that all of our queens have the advantages of the conditions in a normal colony which is about to make a change of queens. Based on many years of practical experience and close observation I find this: When a queen emerges from the cell she is far from being a fully developed insect. She is a white, soft, mushy thing, easily mashed and susceptible to cold and neglect unless held in her cell by the bees as in after-swarming. But in a commercial queen-rearing yard where only one cell is placed in a nucleus, or as in pre-introduction, where a cell is placed in a cage, queens are not so held, and these queens, just from the cells, need a high temperature and the humidity and nutritious food found in a normal colony. And by reducing this in any particular the perfect development is by that much retarded, and the queen is damaged in proportion to the reduction. Imagine, if you can, such high temperature, humidity, and nutritious food, in a little thin box out in a night when the temperature goes down from 38 to 50 degrees, with 50 bees to provide the same. Or in any of the pre-introduction cages provided with candy, as un-nutritious food for the queen, and wire cloth for her to snuggle up against, like a prisoner, which she is, instead of an escort of bees to fondle her, or the expanse of a normal colony to roam in. No, the man who is taking up space in our bee-papers in proclaiming the *improvement* of our bees by selection, by importation, by various crossings, etc., and at the same time advocates rearing queens by the pre-introduction and cupful-of-bees plan, is drifting out on an open sea, without chart or compass."

## General Correspondence

### STOCKING A BEE-RANGE.

**The Problem of Overstocking; Various Causes of Annual Variations and Marked Changes in the Varieties and Quantity of Honey-producing Flora; is a Range Overstocked When the Surplus per Colony Begins to Decrease? Number of Acres Necessary per Colony.**

BY OREL L. HERSHISER.

*Continued from last issue.*

Variations due to climatic conditions are familiar to bee-keepers, as nearly all have felt the effects of drouth and excessive rainfall. We of the North have also occasionally had our honey prospects nipped by frost. In the semi-arid regions, if there is insufficient precipitation in the mountains to provide the needed water for irrigation, there results a short crop of alfalfa honey. Perhaps there is no extensive region where the crop of honey depends so much on rainfall as do the sage ranges of California. So important, indeed, is rain to the California apiarists, that they forecast their honey crop with greater or less precision as soon as a certain number of inches has fallen. However, with some of them near the coast, clouds and fogs set their prognostications at naught.

Variations due to the hand of man are observable wherever the woodman's ax or the farmer's plow-share has operated to subdue the wilderness and render the soil fertile. In times past, excellent basswood locations were plentiful; but now, as the result of the rapid and constant utilization of basswood timber for lumber and other purposes, good basswood ranges are few and far between, and the source of this excellent variety of honey is fast disappearing. Often extensive areas of white clover, wild red raspberry, willow-herb, and other wild flowers appear of their own accord upon the land denuded of the basswood, along with other timber in the process of clearing the land, and, later, alsike clover and buckwheat are cultivated, and thus, usually, is there compensation for the loss of the basswood, for the soil on which it flourished is also adapted to the growth and development of these wild plants and the cultivated ones as well. Again, there are numerous locations, once good as sources of basswood honey, where later flourished wild flowers, and clover, and buckwheat, that have diminished greatly in value as bee-ranges because of the adoption by the husbandman of extensive truck farming, gardening, or the growing of cereals or other non-honey-producing plants as their main crops. On the other hand, many of the best honey-producing ranges in the semi-arid regions were worthless to the bee-keeper until the hand of man transformed the dry, brown, and often bar-

ren wastes into blossoming fields of green and purple.

If alsike clover, buckwheat, or other nectar-yielding plant is found to be one of the main crops of a locality, this fact is significant as indicating that soil and climate are especially adapted to its perfect growth and development, and hence, acre for acre, such a location is more valuable as a bee-range than one where mixed agriculture is the rule.

Such variations as are due to the absence of uniformity in climatic conditions have comparatively little bearing on the proper stocking of a location, as we soon learn by observation and experience, and by consultation of the records of the weather service, what we may expect in the average season.

Those variations and changes that are due to the hand of man have a marked bearing on proper stocking; and if we would maintain the proper and most profitable ratio of bees to forage, readjustment of the number of colonies to the amount of flora will sometimes be required.

Measuring the area of some varieties of honey-producing-plants by the acre is attended with some difficulty. Basswood-trees, as a rule, occupy only a part of the space in the forest, the rest being occupied by other varieties of trees. Much of the goldenrod is found along fence-rows and in isolated bunches of greater or less area on unoccupied lands. White and sweet clover behave in a similar manner, occupying only such soils as are peculiarly adapted to their growth, and the same is true generally of all plants that flourish in the wild state. Necessarily the number of normal acres of such nectar-yielding plants on a bee-range (that is to say, the number of acres there would be if each variety grew on as small an area as possible and produced a vigorous growth and luxuriant bloom) can only be estimated.

The blossoming surface of plants that have a bush or shrub like habit is greater, by reason of its vertical extension than plants the bloom of which is spread out in a comparatively thin horizontal layer. This is true in a more marked degree of trees with spreading tops such as the basswood and apple, and especially where the growing areas are not crowded. Generally the blossoming area of plants depends upon the surface that is exposed to light and sun; and if plants grow thickly they will have a small blossoming surface, and *vice versa*.

It would seem that the matter of properly stocking a location is not so complex after all but that it may be accomplished within such limits as will leave a margin of inaccuracy sufficiently narrow as to be of small financial consequence.

As the result of the testimony of some of our brothers of the craft, and of my personal experience and observations, I should feel that I was fairly near the right point in stocking the location according to the following rules:

1. Wherever soil and climate are adapted

to the full development, both as to growth and nectar secretion, of one variety of first-class dependable nectar-yielding plant, or more than one, if their period of blooming is identical, one colony sufficiently populous to be a prime surplus honey-producer for each  $1\frac{1}{2}$  normal acres of flora within  $1\frac{1}{2}$  miles of the apiary will properly stock the location.

2. Wherever soil and climate are adapted to the full development, both as to growth and nectar secretion, of two or more varieties of first-class dependable nectar-yielding plants that flourish on the same range, and bloom in succession or at different periods of the season, each yielding honey of the same value per pound, and the same quantity per normal acre, one colony sufficiently populous to be a prime surplus honey-producer for each  $1\frac{1}{2}$  normal acres of flora of the variety that flourishes in greatest abundance within  $1\frac{1}{2}$  miles of the apiary will properly stock the location.

**COROLLARY.**—If the varieties of honey are of different values per pound or quantity per normal acre, the number of colonies should correspond with the number of acres of that variety of flora that will yield to the apiarist the greatest value.

Bee-keepers whose locations are understocked are allowing valuable resources that are right at hand to go to waste that could be economically garnered, for the reason that the appliances for running a fair-sized apiary are in a large measure sufficient for running one several times as large. It would seem to be the plain duty of the apiarist to stock his location properly if he desires to monopolize it.

Kenmore, N. Y., Feb. 9.

## SPRING DWINDLING.

### Longevity versus Pollen Substitutes.

BY SAMUEL SIMMINS.

Mr. F. Dundas Todd, page 122, Feb. 15, asks, "Is there a practicable method of giving a substitute for pollen inside the hives?" There are several, some of which he appears to have overlooked. Certainly he had an experience that would make him think hard on just that subject.

Mr. Todd gives a quotation from my 1904 edition, which is rather a condemnation than a helpful explanation of any plan of substituting artificial pollen in the total absence of the natural article. I have seen and known of so much harm being caused by candy fed in winter, and flour candy used at an improper season, that, until the above issue of my work, I had been very much in the same mind as the editor as regards offering various methods of supplying pea flour that I had tried over a period of more than thirty years.

But notwithstanding Mr. Todd found only four words referring to meal, I should like to ask him to take up that same edition of

the work referred to and cast his eye down page 36, where he will find directions for supplying artificial pollen in two forms inside the hive, close to the cluster. The best way that water can be supplied at the same time is undoubtedly by the means of warm thin syrup so placed that it will keep warm all the time.

If the weather should be fair when meal is given to the bees, then no harm can occur; but with a cold and sunless period my own opinion is they are much better without. Stocks have dwindled badly, just because flour candy had been supplied in early spring, and I have always tried to persuade my correspondents to discontinue its use at that period.

### LONGEVITY AND STAMINA.

I have made a law unto myself, that, unless overtaken by disease, there should be no spring dwindling in any modern apiary where any sort of progress is claimed by the owner. His watchword should be *longevity* and *stamina*; and with these points gained he can defy dwindling and short honey crops. There is not even the excuse available that his bees have gathered a lot of honey-dew, as he can always feed enough pure syrup at the latter end, upon which the bees will then feed during the critical period, leaving the poor feed for use when they begin to move freely.

My own district is one that shows a great scarcity of pollen in autumn and spring, so that my stocks, nine years out of ten, winter without that desirable adjunct to their stores. Nevertheless, the bees frequently go from August until April without rearing the least patch of brood; yet I often get two and three frame nuclei (wintered as such) into swarming condition earlier than the established stocks wintered by many of my correspondents, even though they are blessed with an abundance of natural pollen.

The peculiarity of my district has compelled me to select my breeding stock so that workers hatched in August are found still active in May of the following year. So persistently have I bred for longevity that I believe no sort of ordinary neglect, apart from actual starvation, can cause these bees to dwindle; hence the necessity of early brood-rearing is not very important. I might even say its absence is an advantage, as progress is the more rapid when the advent of fair weather provides the necessary nitrogenous food. Possibly few owners have ever established stocks absolutely without pollen at the beginning of winter; but usually one comb would easily contain all I could find among 100 colonies.

In securing the quality of *longevity*, one is sure of obtaining almost every desirable point required in a good honey-getting strain. The stock of bees that loses the least number will always be strong in wing power, and, of course, they build up to full strength in half the usual time. Moreover, they appear to hibernate so perfectly that the stores show little diminution before brood is reared extensively. They require to fly but sel-

dom; and the almost total absence of dead bees before the entrance during winter is one of the most astonishing facts that result from breeding for longevity.

#### BEES STEALING EGGS.

Surely Mr. Frazer, page 108, Feb. 15, does not imagine any one can think fertile workers are responsible for producing a perfect mature queen. He should understand I implied fertile workers were responsible for the eggs found in queen-cell cups, *where no proofs could be offered that those eggs ever came to real queens*. His own experience goes to show that bees may sometimes steal eggs, though he perhaps does not realize that even his imported queen may quite likely have taken a flight, as many fertile queens do, and got into the wrong hive.

In the Feb. 1st issue, however, Mr. Pritchard appears to give a true case of bees stealing eggs. Not only were several queens reared different from those in any of the hives except one weak Carniolan lot, but when those dark bees were removed there was no further trouble.

Then we must conclude that bees do, once in a while, develop this remarkable propensity. But what was there to show that the same bees did not continue to appropriate eggs from some other Italian lot? This is a point the queen-rearer will have to consider seriously, for he will now require to keep his eyes open very wide indeed if he is to be sure he is securing young queens every time from his choice breeder.

Queenland, Heathfield, Eng., March 7.

#### A GLIMPSE AT THE CELERY INDUSTRY OF MANATEE CO., FLA.

BY E. B. ROOD.

At the request of Mr. A. I. Root I will say a word as to one of my celery-fields as illustrated by the engravings. The middle view represents the celery as it is growing in the field, the bleaching-boards having been taken down and the "cutters" cutting the celery for the "strippers," as they are called.

The upper view shows the strippers at work. They take off from the stalks all of the dead leaves and branches so that it is ready for the packers.

In the lower picture the packers are at work. We use in Manatee Co. a crate 12×18×24 inches, and this holds on an average about 3½ dozen bunches of celery. The field shown cut about 850 crates to the acre; and when it was sold it brought \$1.40 per crate, or \$1190 at the depot in Bradentown. The price went as high at times as \$2.20 a crate, f. o. b., but is now worth about \$1.00. I think it costs to raise an acre of celery, and market it, giving it the best possible attention, about \$400 to the acre.

The price of celery land is increasing rapidly, as many successful growers have paid for their lands in a single crop. But it requires lots of work to grow and harvest a

crop like this. If, however, we succeed in bleaching the celery with paper instead of boards, the work and expense will be greatly reduced. Many have tried paper this year, and I am expecting to buy a carload of paper for my own use next year.

Bradentown, Fla.

#### ITALIANS SWARM MORE THAN BLACKS.

Swarming of Italians and Blacks; Italian Colonies get Strong Too Early.

BY W. C. MOLLETT.

The past season I have had occasion to observe again the difference in the swarming of blacks and Italians when run for comb honey. It seems that most of the difference is caused by the greater prolificness of the Italians, which causes the hive to become crowded with bees very early in the season. This is rather a disadvantage, as the first swarm will swarm again in a month or less—something I have never known the blacks to do. Also, the size of the hive has something to do with swarming, as the bees will usually swarm much sooner in a small hive than in a large one. Some writer says that a large hive only delays but does not prevent swarming; but this seems to be at variance with the facts, as it has been proved that a hive that has a brood-chamber large enough to keep the queen busy for 21 days will not swarm nearly as soon nor as often as a smaller one. Of course, locality has something to do with it, as I am fully convinced that bees will swarm more here than they will in a region where the chief honey-yielder is white clover. The chief sources here are whitewood, basswood, and sourwood, coming in about two months' time, from May 15 to July 15. Neither flow lasts very long; but they excite the bees so that they will swarm early and often, especially Italians.

Some seasons I have known strong colonies of blacks to fail to swarm, but have never known the same thing to happen with the Italians in a normal condition. I do not think there is any question as to Italians swarming oftener than the blacks when run for comb honey; but when extracted honey is produced in large two-story hives the swarming may not be much of a nuisance. Some of the Swiss bee-keepers claim to have a non-swarming strain of the black variety; but in this case I think that the question of location must be taken into consideration. I am, however, firmly of the opinion that a non-swarming strain will never be developed from the Italians, and perhaps not from any other race; but I think that much greater chances lie in carefully breeding and selecting the blacks with the object of eliminating the swarming habit.

#### SOURWOOD AS A HONEY-PLANT.

This is a large shrub or small tree which grows on the high rocky parts of the Appalachian ranges and foot-hills. It blooms in

A CELERY-FIELD AT BRADENTOWN, FLORIDA.

The upper view shows the "strippers" at work—mostly colored women and girls. The middle view shows how they harvest the crop after it is grown. The lower view—packing the celery in boxes ready to load it on the cars.

GRAPEVINE TRELLIS FOR SHADE.

the early part of July, and continues in bloom for about three weeks, having a small white drooping flower. It is a very good yielder of extra white honey which is of a very thin nature, and does not granulate to any extent. On account of the favorable weather when it blooms it is one of the surest sources of honey where it abounds; and also on account of the trees being small and the wood of little value it is not liable to be cut off as close as whitewood and basswood. The honey has a somewhat stronger flavor than that from basswood, but is considered here as very fair honey, and always sells for a good price, as it is as white as or whiter than that from basswood.

Stonecoal, W. Va., Feb. 14.

### GRAPEVINES FOR SHADE.

BY W. M. O'NEEL.

My apiary is located under a grapevine trellis for shade, as shown in the engraving. The posts for the trellis are set 8 ft. apart each way, boards  $1\frac{1}{4}$  inches thick and 8 inches wide being nailed on each line of posts, and crossing each other at right angles by means of notches at the post. These project 30 inches on all four sides; 12 inches from both sides of each board is a galvanized wire, and on these wires and boards the vines are trained, leaving an open space for the flight of the bees between each four posts. This space, about 5 feet square, also lets in plenty of light and air.

This plan affords a good open shade, which is much better than the dense shade of the

apple-tree at one side, which is too dense on damp or cool days. The grapes pay me well for the expense and trouble. While the grapes were getting a start, the Kudzo vine, the flowering bean, and the tender moonvine gave excellent shade temporarily.

### CONCRETE FOUNDATION AND ALIGHTING-BOARD.

The other engraving shows a close view of one of my hives under the trellis. This hive rests on a concrete slab for a foundation, which I find cheap and serviceable. These slabs are made with a hinged mold, and are two inches thick. They are half an inch narrower than the bottom-board and six inches longer, the extra length being tapered down to a thickness of half an inch at the front end, making an excellent alighting-board. When these slabs are leveled on good solid ground they stay in place, and do not sink down nor get out of level. They are reinforced both ways with old barbed wire. The expense was not over 15 cts. each, including my time for making.

### A VISIT WITH HAWAIIAN BEE-KEEPERS.

BY E. F. PHILLIPS.

It was the writer's privilege during the winter of 1908 to visit the Territory of Hawaii and to meet the bee-keepers of the islands. These islands, which form one of our outposts, are, from a bee-keeping point of view, of exceptional interest. The methods of management, the honey sources, and the tropical conditions under which the work is

carried on, are things entirely new to one who has studied bees only under our mainland conditions, and there are many things to be observed there which will probably interest other commercial honey-producers.

The area now covered by apiaries does not equal Rhode Island in size, nor is all the available area as yet covered. The bee-keepers are at present extending their operations, and it will be but a few years before they make a larger showing. They have already shown that they are progressive, and their methods of management are thoroughly modern.

While there is a season during which there is less honey coming in, there is no definite honey-flow such as is found in most places on the mainland. On the contrary, there is something coming in almost every day in the year. As a corollary the flow is not so intense but the bees keep right on at a moderate rate adding to their stores. The old tradition that bees in the tropics do not store excess honey is certainly disproven by results on the islands.

The main floral honey source is the algaroba-tree, closely related to the mesquite of the Southwest. The honey is white, and granulates rapidly, resembling most our alfalfa honey. During the spring and early summer (if we can designate seasons in such an equable climate) the bees work vigorously on the algaroba. The most interesting

phenomenon, however, is the second large honey source. The bees of the islands annually gather tons of honey-dew honey from the secretions of the sugar-cane leaf-hopper. Such an extensive gathering of honey-dew to form a commercial product is a thing which is unknown to the writer in any other locality. This honey-dew honey does not resemble the honey-dew honey generally found on the mainland. It differs in flavor, and, when relatively unmixed with floral honey, does not granulate, even after a period of years. This product is sold as "honey-dew honey," and finds a ready market among bakers. It could not be used as a table honey, and the producers make no effort to use it in competing for that market. Since leaf-hoppers are always present in numbers on the cane, the flow from this source is practically continuous. During the algaroba flow, or when other nectar-producing plants are available, the bees prefer the floral nectar.

According to the decision of the Pure-food Board, the product made by the bees from the secretions of insects may be sold as "honey-dew honey." It is a natural product gathered by the bees, and unmixed with any added sugars. Since there is a market for this product there is no reason why it can not be sold provided it is so labeled that the buyer knows what he is using.

A point of considerable interest in Hawaiian bee-keeping is the fact that there are few small bee-keepers and almost no amateurs on the islands. Bee-keeping is a commercial industry, and most of the bees are owned by corporations. By such organization one competent bee-keeper can superintend the work with several thousand colonies, the actual manipulation being done by laborers. This reduces the cost of production, and such a plan seems to foreshadow the future of mainland commercial apiculture.

The Hawaiian bee-keepers are extremely fortunate in that they have among their bees no contagious disease. Either American or European foul brood would cause enormous losses under such tropical conditions, and it is to be hoped that effective quarantine regulations may be established to prevent the introduction of these plagues which annually cause so many thousands of dollars' loss on the mainland. Steps have already been taken in this direction. It is doubtless true that the bee-men of Hawaii would control a contagious disease as good bee-keepers do elsewhere; but if they can prevent the introduction of the causes they will be relieved of much troublesome labor.

Aside from these special features, Hawaiian bee-keepers face the same problems as do their mainland co-workers. They are good examples of what a progressive bee-keeper

CONCRETE HIVE-STAND AND ALIGHTING-BOARD.

should be, and should have the cordial cooperation of the mainland leaders in apiculture.

Washington, D. C.

### TRANSFERRING FROM AN OLD STUMP TO A MODERN HIVE.

BY CHARLES M. KOLB.

The engraving shows an oak stump and a Danzenbaker hive, representing the old and the new home of my bees. I found the colony in November, during the gunning season, and in February found that they had wintered well. Up to this time I had never handled bees nor seen a hive, except at a distance, but I wished to take them home; so I tacked a piece of wire cloth over the hole in the stump, and cut off the trunk of the tree above the hollow part. I then sawed off the stump close to the ground, turned it over and tacked a sheet of tin on the bot-

COLONY TRANSFERRED FROM A STUMP INTO A MODERN HIVE.

tom. After hauling it home, a distance of four miles, on a wagon, we placed it in the yard on a flat stone, and removed the wire cloth from the entrance. The next day being warm the yard was full of bees.

Later, my friend and I sawed the stump in two, took the combs out and filled six of the Danzenbaker frames with brood and honey, tying them in with string. We placed the hive where the stump had stood. For three days and nights the bees worked cleaning house and making repairs, removing dead brood and rotten wood.

We found that we had the hive located too close to the sidewalk, so we moved it forward three feet every day, and on the fourth day we reversed the entrance so that it faced the old location. In all, we moved the hive 75 feet to the rear of the yard and the bees followed it without any apparent concern. Occasionally one would drop to the old location, circle around, and then shoot into the hive.

Haddonfield, N. J.

### DO HONEY-BEES PERFORATE THE NECTARIES OF FLOWERS?

BY JOHN H. LOVELL.

*Mr. Root:*—After reading your comments on page 214 I am inclined to think that you are right, and that there is at present no satisfactory evidence of *honey-bees* perforating the nectaries of flowers. I would use the term "nectary" in a strictly technical sense; for, as I will show, honey-bees do pierce succulent tissue. Perhaps they have not sufficient strength to puncture the walls of nectaries, which are frequently tough and thickened. I have been unable to find any reliable records of honey-bees biting holes in flowers. In one instance, as mentioned in my paper, I observed a honey-bee apparently attempting to puncture the spur of the touch-me-not; but it is not all unlikely, as you suggest, that there may have been already a small hole, which it was seeking to enlarge. The holes were, however, undoubtedly made by bumble-bees, for the beetles and spiders seen in the flowers were far too small and few in number for this purpose. The number of flowers with the spurs punctured was very large.

On the other hand, there is not the slightest reason to doubt that bumble-bees frequently puncture flowers. They have been seen to do so by many observers besides myself, as Mueller, Knuth, etc. In the case of the scarlet runner, the flowers were visited only by bumble-bees and honey-bees, and were promptly punctured as fast as they matured. If we exclude the honey-bees, there were no other insects present, except the bumble-bees, which could have done this work. Wasps do not visit these flowers since they are short-tongued insects, and the nectar is inaccessible to them. While wasps can masticate other insects, I have never read of an instance of their puncturing flowers. In all the other cases mentioned in my paper the bees referred to are bumble-bees.

I have just examined the maxillæ and mandibles of a worker of the honey-bee under the compound microscope, and compared them with the same mouth-parts in a worker of *Bombus terricola*. While they are essentially alike, smaller differences can be easily discerned. The lacinia of the bumble-bee appear narrower, more rigid, and more acutely pointed, while its mandibles are toothed at the apices, and those of the honey-bee are entire. Still if the honey-bee is strong enough I should think it might be able to puncture floral leaves; but this is perhaps the difficulty—it is a less powerful insect than the worker, and not to be compared with the queen bumble-bee, and it probably has not sufficient strength to puncture nectaries. The maxilla of a bumble-bee or honey-bee is composed of two joints—a basal part called the stipes or stipe, and a blade-like terminal part called the lacinia. According to Mueller the lacinia are sharpened at the ends for the purpose of

piercing succulent tissue. Now, while the honey-bee may not puncture nectaries, it certainly does pierce with the laciniae succulent floral tissue.

There are a number of plants which produce succulent tissue instead of nectar into which bees and lepidoptera bore for sap. In the common laburnum (*Laburnum vulgare*) there is a round fleshy swelling at the base of the standard (a large, upright, showy petal well shown in the sweet-pea), which bees and butterflies pierce for the abundant sap. There are also several species of orchis (*O. morio*, *O. maculata*, etc.), in which Darwin, though he examined them repeatedly under the most favorable conditions, was never able to find "the smallest bead of nectar." Sprengel called them "sham-nectar producers." But the inner membrane of the flower-tube is a very delicate structure, and beneath it there is a copious supply of fluid. Mueller observed a honey-bee pierce this tissue a number of times. "On June 13, 1870, a hive-bee flew before my eyes into a flower of *O. latifolia*. It pierced the inner wall of the spur several times with the points of its maxillæ, and then flew away, bearing the pollinia on its head to a flower of *Lycchis flos-cuculi*. I gathered the flower immediately after the bee left it, and found the punctures visible from the outside as small bright elongated specks."

The flowers are more frequently visited by bumble-bees, which also puncture the tissue. "It is certain," says Mueller again, "that the bees pierced the delicate inner membrane and sucked the included fluid. They doubtless pierced the tissue quickly and easily with the points of their maxillæ." Mueller's observations are confirmed by those of Darwin.

The ability of purely suctorial insects to pierce plant tissues is much greater than is generally supposed. Darwin tells of a moth in Queensland, Australia, which with its wonderful proboscis can bore through the thick rind of an orange. At the Cape of Good Hope the moths and butterflies are said to do much injury to peaches and plums by puncturing the unbroken skins. Darwin also observed a fly (*Empis livida*) pierce the tissue of an orchis. The boring for sap among insects, says Mueller, is much more usual than was formerly supposed.

I have examined a great number of perforations in flowers belonging to various species, and would divide them into two classes—those made by the mandibles, and those made by the laciniae of bees. When the nectary is larger, as in the columbine, two small holes will often be found side by side, made, I believe, by the pinching of the mandibles together, unless each lacinia is capable of making an independent hole. But when the nectary is smaller and linear, as in the touch-me-not, there will be found a narrow slit made by the ends of the maxillæ. Very likely these latter organs are also used on the larger nectaries also. During the coming summer I hope to determine the exact behavior of both bumble-bees and hon-

ey-bees in regard to puncturing the nectaries of the scarlet runner. It would seem as though bumble-bees, being the stronger insects, especially the queens, make the holes, and that the weaker workers of the honey-bee observe and make use of them.

Waldoboro, Me., April 6.

## SWARMING CONTROLLED BY REMOVING BROOD.

BY LEO E. GATELY.

While it is by no means impossible during a good year to double a given number of colonies, and at the same time obtain an undiminished amount of surplus honey, many wish to avoid increase, and in all large apiaries it is necessary to control the tendency of the bees to swarm.

By keeping the force of colonies intact throughout the season, it is not infrequently supposed that they can be kept in ideal condition for working in section supers. Not only is such a supposition only partially true, but to prevent such from swarming, it is at the last usually necessary to deprive them of all or most of their brood by shaking or otherwise.

There are methods whereby, with small labor and without so much as ever seeing a queen, swarming can be readily kept under perfect control.

Two or three weeks before the flow, or sooner if there is danger of swarming, a third section, filled with sheets of foundation, is placed between the two divisions of my brood-chambers. A week later the bees are smoked out of the upper brood-section, and it is replaced by a super. In another week the lower section is removed, and replaced by one containing foundation or empty combs. If needed, a second super can at this time be inserted.

Any plan that rids the hives of all brood kills swarming as effectually as though it had occurred naturally. As described above, it is taken so gradually that the bees do not become dissatisfied and sulk, and there is left at all times sufficient young larvæ to prevent swarming out, as frequently happens with shaken swarms.

With deep frames, as soon as the hive is filled with bees, a second story, usually consisting of one or two sections of my divisible hive, according to the strength of the colony, is placed above. Immediately upon the occupancy of this second story by the queen it is removed to a new stand, and the old brood-nest supplied with a ripe cell.

The return of old bees from the hive placed upon the new stand so depletes its force that all danger of its swarming is removed should it be kept for increase. Now, by placing an excluder under the second story ten days previous to making the division, the old brood-nest is absolutely prevented from swarming, as by that time there will be no larvæ left of a suitable age for starting cells. Usually, however, such precautions are un-

necessary if sufficient super room is given the old brood-nest. By either plan there is absolutely no handling of frames, and the apiarist is independent of any whim of the bees as to their swarming. In a large apiary no professional honey-producer would at the present day think of allowing natural swarming, uncontrolled; and the above methods will especially meet the requirements of all those who wish to avoid the discomfort of watching for even first swarms.

Ft. Smith, Ark.

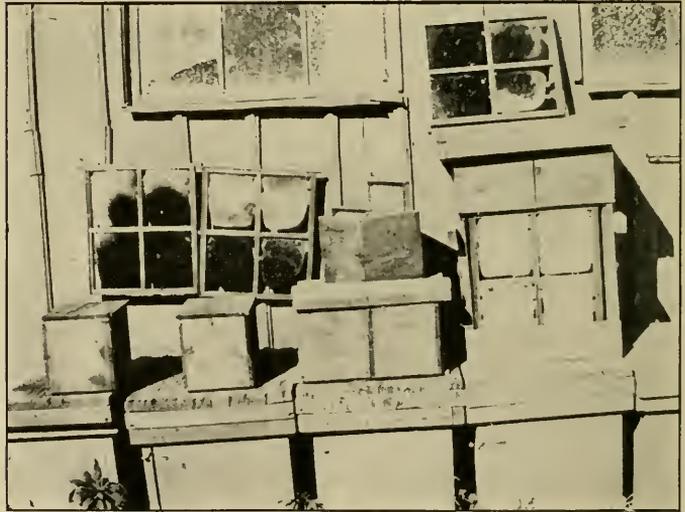

### THE TWO-POUND SECTION OF FORTY YEARS AGO.

BY H. R. BOARDMAN.

Years ago, although I had been using movable-frame hives, I had as yet nothing better than mere empty boxes for my surplus comb honey. I began trying to find something more convenient and more elegant, and the sectional honey-frame was the outcome of my thought. I used these for all of my comb honey for several years. They were plain nailed frames of such a size that four of them would fit in one of my large deep brood-frames. They were prepared with plain wax starters, and were tiered up in a regular hive-body over a brood-chamber. These were quite an improvement, and the best in this line that I had then found. A box to hold the set of sections soon followed, which also proved to be very practical. I made a few of these at first, and soon afterward ordered material for a large number. The interchangeable feature proved valuable in many ways. Four of these boxes covered a hive, and the sections held from  $1\frac{1}{2}$  to 2 lbs. of honey each.

I do not think that I ever produced finer honey or secured better crops than I did in these original sections; nor have I been able to make my business pay any better than it

TWO-POUND SECTIONS AS USED BY MR. BOARDMAN FORTY YEARS AGO.

The small boxes are nucleus hives for queen-rearing, in which these large sections were used as frames.

did then. My first shipment of comb honey was in these sections, for, of course, I had then never heard of a section that would fold, of comb foundation, nor of separators. Well, I shipped 300 lbs. to W. P. Southworth, in Cleveland, at 25 cts. a pound. This looked like quite a deal to me then. But the honey was reported in bad shape, as it was broken in transit, so that I had to take 20 cts. I have often thought since that I would not consider it a great misfortune now that would compel me to accept 20 cts. a pound for my honey.

When the queen got up into the upper part and used these sections for brood-rear-

ing, the idea of putting these small combs in the boxes and using them for nuclei was at once suggested. When the queen which had been placed in the nucleus hive became fertile and commenced laying, the sections were slipped back into the frame, which frame, with the bees and queen, was put into another hive that contained no queen. For several years I raised queens for my own use, and also a few for my friends, making use of these "baby nuclei." This was only a side issue with me, however, as I was not a professional queen-breeder and never have been.

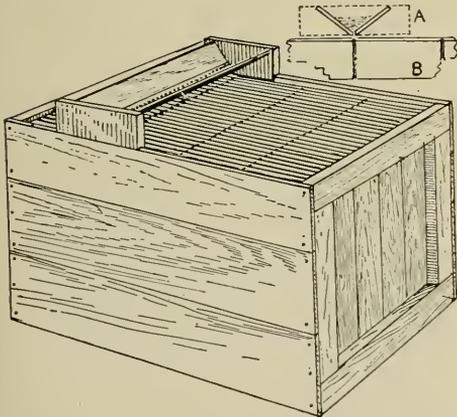

Last summer I brought these fixtures out from the dust and cobwebs of the shop attic, and used them again as I did nearly forty years ago. The illustration shows the small nucleus hives and the manner in which the sections were inserted in one of my large frames. The removable side of one of the hives is also removed, showing the sections of comb honey and also others used for brood-rearing.

Collins, Ohio.

### A SECTION-DAMPENER.

BY WESLEY FOSTER.

We have used all sorts of things to dampen our sections, from a dipper to a syringe; but this trough arrangement does the work better than any thing else we have tried, and much more quickly. The sections are left in the crate, and the perforations in the bottom of the trough are made the same distance apart as the grooves in the sections,

approximately one-sixteenth inch. Warm water is used; and when one row of grooves is wet, the trough is moved over to the next row. The trough would work somewhat better if the sections in the crate were all turned one way, then every groove would be almost certain to be dampened clear to the bottom of the crate.

Water is used pretty freely, and it is best to dampen the sections several hours before folding them, so the water not absorbed will

run off, and the sections that get a too generous wetting will have time to dry out a little.

Boulder, Colo.

[This scheme for dampening sections would be all right, but we should think it would not work much further than a single row deep.—ED.]

### IS A NON-SWARMING RACE A POSSIBILITY?

#### Is the Swarming Tendency Due to Habit or Law?

BY DR. A. F. BONNEY.

If for no other reason than that some of my bee-keeping friends might be happy, I hope the dream of a non-swarming strain of bees may become a reality; however, the more I think of it the more doubtful it appears.

There has been very much written on the subject, I know. I should not be surprised to learn that the ancient Egyptian bee-keepers voiced a wish—but, wait! "It is not our knowledge but our ignorance of the past which constitutes the pride of the present," so perhaps that old-time folk knew more about bees than we do. They trained cats to go into the water to catch fish, though now Puss has a fit if she gets her dainty feet wet.

The first question which comes to my mind when I get to discussing this question is: "What is swarming?" It is not atavism, for that is merely a reversion to ancestral characteristics, a returning to shape, color, or other physical characteristics; nor is it instinct, for that is a special innate propensity in any organized being, but more especially in the lower animals, producing effects which appear to be those of reason and knowledge, but which transcend the general intelligence and knowledge of the animal. Intuition is entirely an unconscious mental process, so it is not that. It is not heredity, for that is almost synonymous with atavism, the transmission of mental and physical characteristics from parents to offspring. I believe this was fully understood by the old philosophers. "I will visit the iniquities of the fathers upon the children, even to the third and fourth generation of them that hate me."

Dr. Jones, in advertising his non-swarming discovery, alludes to the "swarming habit of bees." But is it a habit—a usual or customary mode of action, something which may be acquired and afterward laid aside? "Habit," says the dictionary, is "a mode of action established by use so as to be entirely natural." It would really seem that the definition would apply to this characteristic of the bees; however, the word does not seem to fit entirely, so I ask again, and in all seriousness, "What is swarming?"

In time past, many things were believed which we now smile at. That the lion would not touch the true prince was as implicitly believed a few generations ago as is any church dogma to-day. The world was

flat; slavery was a divine institution. Shall we in another generation look back at the idea of a non-swarming strain of bees and smile indulgently? That many bee-keepers long ardently for such a thing, and believe it possible, is not evidence, logic, nor reason. Consequently we are free to discuss the matter fully and freely.

What is swarming? It is something which is to the bee what family-forming is to human kind? That the young stay and the old go from the hive, and the young go and the old stay in the human home is only a different way of obtaining the same result, if, mind you, we may argue from man to bee and bee to man. Swarming, then, is not a habit with the bees any more than it is a habit for the young couple, impelled by love, to go, gladly and unafraid, into a new world and to a new home. Unsex them and they would not mate and leave the home. No; swarming is not habit; it is law, a part of the sexual plan of the bees. It may even be that the almost sexless workers take this way of mourning their lost queenhood. It is law; and he who violates God's law perishes. Do the bees commit such a violation when they fail to swarm? There are men who do not marry, and there are bees which do not swarm. Let us suppose there were no marrying (a condition said to exist only in the other world); how long would the human race exist? Suppose all the honey-bees in the world were to die save one swarm (a not impossible idea), and that these, for any of many reasons, failed to swarm, and that in the dead of winter the queen died. The unfortunate insects could not fulfill the law, and they would perish utterly; and no one may ever know how many types of animals, birds, and reptiles have become utterly extinct from inability to comply with the law of propagation of kind.

By breeding, selection, we influence the shape, size, color, and even the disposition of the lower animals, and to some extent the characteristics of the insects; but in working with the chickens, if we keep the pullets shut away from the males the eggs they lay will not be fertilized; and if this were persisted in the chicken family would soon vanish. God cursed Onan. Lot's daughter knew the evil of non-swarming. In olden times a barren woman was despised, for perpetuation of kind was a law highly esteemed before these days of swift and easy divorces and race suicide.

Thus it will be seen that, when we take up the study of the exact meaning of words, habit is not the one to apply to the swarming of bees. Rather it is a law peculiar to them. Humans migrate, and that is the only human act which bears any relation to swarming.

It is, I think, permissible to discuss this matter. Were it possible for us to get the queen to mate in the hive, or to have two or more queens in the hive until a new swarm were ready to fly, we might have some hope of creating a non-swarming strain; but we can not; and to attempt to we must upset,

not a habit of thousands of generations of bees not to go contrary to instinct or inherited traits, but law, and one of the fundamental rules of their being. However, there is nothing in the economy of the human to compare with this law of the little people; hence we can have no conception of their mental processes, if they have reasoning faculties as sometimes seems. Having nothing but subjective evidence it is a question if man will ever be able to reduce this tendency to swarm; for, consider keeping a swarm of bees in a hive, room, or cave, five, ten, or even fifty years without swarming is not evidence that we have destroyed the tendency to do so. It merely means that we or our environments have put the bees into a condition where it is not necessary for them to swarm. They probably had more comb than they would ever fill, and simply went on superseding as the age of the queen required. Moreover, it is very likely that in cave or house room there were more than one "swarm," two or more queens. This is reasonable from what we know. Even if we did keep a lot of bees as above described for scores of generations of bees, is it not a fact that, if they were placed in normal surroundings again, crowded for room with a big honey-flow on, they would at once swarm? They certainly would, for *they are wild by nature*. Man has never domesticated them. In all the thousands of years he has been handling them he has not made a start to tame them or bend them to his will. Give a swarm the nicest hive, with every thing an honest bee might reasonably be expected to ask, and when they come to swarm they will leave the yard, seeking a dirty rotten tree, even though there were a dozen empty hives in the yard they left.

I have expressed the opinion that a certain method of preventing swarming might be used to overcome slowly the tendency of bees to swarm. However, I now think, and I believe time will prove the correctness of my conclusions, that even with that carried on for scores of generations of bees they will swarm just as soon as they get from under man's control, because they *are* wild by nature. They were created so, or developed to be. They are impelled by a law of which they have no knowledge and which they have no wish to violate. It is a part of their sexual plan, just as home-making or family-forming is part of the human plan, of which the young folks have no knowledge. They only know they are in love, but that is quite sufficient.

A man came to me once with an invention. He proposed to wind a rope on a shaft. At the rope's end was a weight, which, falling, unwound the rope and thus gave power to do work. He found in time that the falling weight would lift less than the man could lift in winding up the rope. Many of my brother bee-men are trying to develop a strain of non-swarming bees with the idea that they are dealing with a *habit*. Are they?

Buck Grove, Iowa.

### AN ANTI-SWARMING DEVICE.

#### Additional Clustering Space Furnished without Altering the Hive or Otherwise Changing the Equipment.

BY WALTER S. POWDER.

Through the courtesy of Mr. H. Junge, of Cumberland, Ind., I am submitting his description of a new device which can be added to any hive, thus making it a non-swarming hive. To get an idea of the construction, just imagine a super filled with fences, using narrow cleats on the fences to maintain a three-sixteenths bee-space. The device can be arranged at the entrance, or it can be placed beneath the brood-chamber of any hive. Mr. Junge informs me that every experiment has been a success thus far.

We have long known that a very deep entrance to a hive would do much to retard swarming, and Mr. Junge has taken advantage of this idea, but at the same time permitting an abundance of ventilation, which is very important during a honey-flow. Personally I should prefer placing the device beneath the brood-chamber, and it has the advantage of being inexpensive and very neat.

Indianapolis, Ind., Dec. 1.

[The following is Mr. Junge's description of his device.—Ed.]

The patent application on my device was worded so as to cover it whether attached to the hive above, below, or at one side of the brood-chamber. I am not yet certain where it should be located. Fig. 1 is a bottom view of the device, arranged to be placed under the brood-chamber. This was the construction that I first thought of. For a trial it was placed under an eight-frame brood-chamber, the colony in which was cluster-

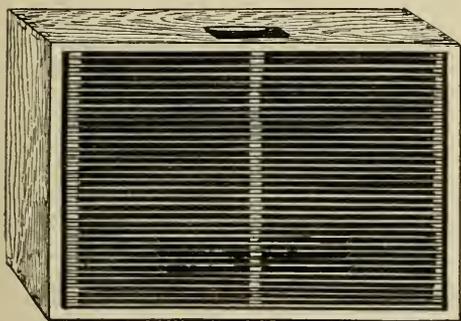

FIG. 1.—Junge's anti-swarming device arranged for placing under the brood-chamber. Patent applied for.

ing out heavily, and, to all appearances, was ready to swarm. Shortly after the change was made, the bees stopped clustering on the outside of the hive, even during the hottest days, and showed no further inclination to swarm. This colony made a better showing than most colonies in this neighborhood.

Fig. 2 shows another form of the device, designed for attaching to the front of the hive. If this will do the work as well as the one under the brood-chamber I am inclined to believe that it is the better construction

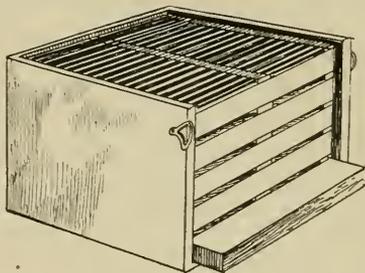

FIG. 2.—The anti-swarming device for use in front of the hive.

of the two for the following reasons: It can be much more quickly attached than the construction shown in Fig. 1, and there is no necessity of using smoke or otherwise disturbing the bees. It may be left on the

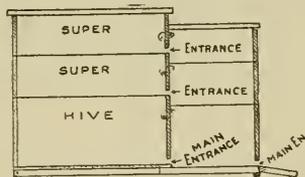

FIG. 3.—A provision for use with plural entrances.

hive permanently. It is separated, of course, from the hive proper by the front wall of the hive, so it could not possibly make it more difficult for the bees to keep warm in winter. It will also, to a certain extent, check sudden changes in temperature. Furthermore, those who prefer plural entrances can adopt this plan very easily; for with every comb-honey super put on the hive a corresponding slatted super of like height can be put over the anti-swarming attachment, as shown in Fig. 3. In this way there are plenty of entrances, but still there is no chance for a draft, and there is, besides, but one main entrance for the bees to guard.

Cumberland, Ind.

### VENTILATION TO CURE SWARMING BY THE DR. MILLER PLAN.

Is the Cure Worse than the Disease?

BY O. B. METCALFE,  
The New Mexico Chap.

Dr. Miller discusses "ventilation to prevent swarming," p. 691, Nov. 15, 1909, and the editor calls for reports. This question of ventilation is no new thing with Dr. Miller, and he has had me trying it, more or less, for the past three seasons. In a way, I am now about to turn against his plan.

Experiments and observations have convinced me that swarming may be much reduced by ventilation; but let us go slow with this method of swarm control, lest we blindly administer a remedy which is worse than the disease, for I have also noticed that a colony which is given as much as a  $\frac{3}{8}$  entrance seldom stores the surplus that one does when kept well shaded and left on a  $\frac{3}{8}$  entrance throughout the season. Now, the question I am raising is, "How does ventilation prevent swarming?" If I understand the swarming impulse, it is *incited* by the bees filling their hive with honey and brood, while conditions continue favorable for rapid brood-rearing, and is *checked* either by giving the colony more room or by stopping the queen in any way from laying at her best. Now, ventilation certainly does not add room, so perhaps it retards egg-production, and I think I have been able to note that it does. Who knows for sure? Until I know more about it I shall restrict ventilation experiments to a few hives, and give the most of my bees store room and brood room. When they will not make comb honey they may make extracted; and when a colony gets the swarming fever so badly that it won't stay at home, even to make extracted honey, it shall have a nice young queen, unless I desire increase in that particular yard.

Mesilla Park, N. M.

[This is a live and important subject. We should be pleased to hear from others.—ED.]

---

### IS THERE A "BEST BEE" ?

Have the Italians been Given too much Credit?

BY D. M. MACDONALD.

I have been a student of American bee literature for about twenty years; and during the last dozen of these, little if any thing has escaped my eye. The feature of all others which has impressed itself most on my mind is the all but universal cry in favor of Italian bees. The pean of praise runs something like this:

"I have foul brood in my hives. What can I do to rid myself of it?"

"Get Italians," is the prompt reply.

"Wax-moth troubles me a lot. What is the best cure or preventive?"

"Italianize your bees, getting rid of the blacks," comes the inevitable answer.

"My bees seem to be working into scrub stock. What can I do to energize them?"

"Purchase Italian queens," comes the advice sure and quick.

"My bees are so vicious that working among them is becoming a terror to me. What would you advise me to do?"

"Get Italians, and you can handle your bees as if they were flies."

Now, my object in noting all this is not to rail against Italians. They must be good bees in America and for America; but I ob-

ject to having it so reiteratedly dinned into our ears that they are the *only* bee, and that all other races are anathema.

A good many years ago I put in a plea for blacks, and recorded some twenty points where, in this locality, they took precedence of their cousins. You were good enough to extract some of my points and reprint them in GLEANINGS, but with some remarks added which read very much like a point of interrogation after each. Four of them were similar to the quartette I have named in my opening sentences. I will deal with each.

Moths are at times an undoubted nuisance. In your A B C you give Italians as both a preventive and a cure. I raise no question of your correctness; but I do to the fact that you confine the extirpation to the influence of one class of bees. I may point out the fact, on the other side, that during over twenty years I have never had a comb mutilated by the depredations of wax-moths, either *Galleria* or *Achroia*; nor do I know of *any* bee-keeper, who attends to his bees, who gives even a passing thought to this at times deadly enemy. Yet all over the three countries—England, Scotland, and Ireland—the blacks stand in the ratio of 80 per cent to 20 per cent of all other races. The secret of immunity, therefore, does not lie in the possession of Italians. You will find it on page 165 of "Cowan's Bee-guide," last line. "If hives are kept strong in bees the wax-moth need not be feared." I do not claim a monopoly of this wisdom for this side of the Atlantic, because if you turn up Quinby (1866), page 244, you will find that he italicises the fact that "only when we know that all our stocks are full of bees" are we safe from the incursion of this troublesome pest. Then we are immune whatever the race of bees may be.

If we have had one (so called) fact more than another emphasized over and over, it is that Italians can cure foul brood. I know that they have brought the fell disease both to myself and others, but I have yet to learn that they are any more preferable than our own blacks in warding it off or aiding in effecting a cure when it finds a lodging in any apiary. GLEANINGS, as consistently as any other American journal, has extolled the virtues of Italians in working a cure; but I note of late that its editor is taking broader views, as on page 89, where he says, "It is possible that, in certain localities, there is a strain of blacks that will resist the plague as much as or more than the Italians." That is just my contention. Dr. Miller, p. 100, gives corroborative evidence: "Any extra immunity is derived, not from the fact that they are Italians, but because of their extra vigor. If you get that same vigor in any other bee you will get the same immunity." Our blacks, I maintain, have that vigor, and so have the well-bred queens of the same race reared under proper management in Germany and Switzerland. In very few countries has foul brood been put under subjection more completely than in the lat-

ter country, and, working for its suppression, their inspectors find black blood no detriment. Of the two races, the preponderating vote would be in favor of blacks.

Perhaps all bees have a tendency to revert to scrub stock at times; but of the three or four chief races, blacks are that way the least inclined. Take Carniolans, Italians, or Caucasians, and what a fight there is to keep the stock pure, with even a moiety of blacks in the neighborhood. Does not that prove blacks to be the predominant race? In a very few generations all the golden color vanishes. Here the Italians are a "soft" race. Just recently you yourself said of yellows, "Experience shows that bees bred for color will not stand as much cold as the dark strains that appear to be more nearly the normal type of the race." Mr. Byer has repeatedly spoken a good word for the darker races, and in the February *American Bee Journal* he says that, for "good wintering and for brood-rearing in the spring under adverse conditions, Italians are simply not in it." My own experience is certainly in favor of blacks building up and keeping up their strength more uniformly than any other race, and they *don't breed untimely*; consequently a smaller colony will yield a larger surplus. Given a batch of young black queens and a like number of Italians, the weeds in the last lot will number three to one of the others. While we get more powerful individual stocks of Italians than blacks, yet all over an apiary a higher percentage will be scrub stock, and far more stocks will be found queenless from no apparent cause.

Much has been written on the subject of vicious bees. No race is gentler and more equitably tempered than Carniolans, under almost any conceivable set of circumstances. Some Caucasians are gentle, but others are the reverse. All agree that Cyprians and Holy Lands are about as cross in general as bees know how to be. Italians (and, as a rule, the first cross) are found on the whole to be thoroughly amenable to manipulation in this country; but further than that we had better not inquire. Italians, on first opening the hive, cling to the comb and appear quieter than blacks, which appear more excitable; but as the manipulation goes on, give me the blacks almost every time. Moses Quinby describes this trait: "I can often avert a black bee in time to prevent a sting; but he must be a skillful swordsman who would thus parry the lightning thrust of the Italian." A writer on page 109, GLEANINGS, says, "The crossiest colony we have are yellow Italians, and the gentlest are dark hybrids."

For comb-capping and high finish of section honey the blacks are unexcelled. They are excellent nurses, fairly prolific, not given to excessive swarming, admirable defenders of their hives, thoroughly suited to our variable climate here, splendid winterers, raise brood only in season, and are long-lived; and they *do* resist the wax-moth and aid us in curing foul brood; are gentle to handle, and

keep up their vitality, thus avoiding scrub stock.

Banff, Scotland.

[Our correspondent has made an exceptionally strong plea in favor of the black race, or at least that race as it is found in Europe. If any other correspondent or reader has found the black bees are better for his purpose, and has hesitated to say any thing about it because he thought the editor might be prejudiced, we desire to say to him right here and now that our columns are open to further discussion of the subject. If we are prejudiced in favor of Italians it is because the great majority of the American bee-keepers are in the same boat. It is possible and even probable that local conditions have shown that the Italians are better than the native American blacks. We say *American* blacks, because, apparently, the English bee is superior.

The great preponderance of this dark race in "Merrie England" may be due to the fact that a very large number in that country do not use the modern frame, but the old-fashioned straw skep. In saying this we do not mean to suggest that the English bee-keepers are not as progressive as those in America—far from that; but there are many cottagers in that country who can not afford any thing better than a straw hive. Blacks being native bees they would naturally use them.—Ed.]

#### THE PIPING OF A VIRGIN WITNESSED.

The Sound Not Made by the Wings.

BY F. DUNDAS TODD.

My friend Mr. Russell recently had the following experience: In one of his hives were several queen-cells; so one day he opened it with the intention of securing a few for nuclei. On taking out the first frame he saw a young queen on it which he at once secured. On lifting the second frame he heard the call of a young queen, and at once spotted her. Understanding there was some little dispute as to how the sound was produced he watched her very closely, and noticed that the wings were perfectly still. The call evidently was emitted from the thorax. In his boyhood, thirty years ago, his father had owned several skeps, and at that time the piping of the young queens had interested him greatly, so he watched this one for several minutes in order to find out the meaning of it. This virgin ran along the comb, about an inch at a time, stuck her head into an ordinary brood-cell, then emitted the call. He watched her repeat this performance at least a score of times. To confirm his observation he called his wife, who agreed as to the details.

Mr. Russell's supposition is that the virgin was looking for her rivals. The important point of the observation is, I take it, that the wings were perfectly still, thus showing they were in nowise concerned in the production of the noise.

Victoria, B. C.

## Heads of Grain

from Different Fields

### NATIONAL ASSOCIATION.

The membership to-day, March 26, is 3700. The president's mark of 5000 is fast coming in sight. Let the good work go on.

Information Bulletin No. 15 has just been mailed to members. This is of value only as each member uses it. To many it is worth the dues of several years.

The second edition of "Bee-keepers' Legal Rights" has just been mailed to the members. It is a reference volume which every bee-keeper should have in his library. Paid-up members get a free copy. There are none for sale to outsiders.

The winter losses of bees are quite heavy in some places. Some report a loss of three-fourths.

The present honey prospects are good except in Southern California, where they have had no rains for nine weeks.

Each new member gets a copy of the 1909 annual report free, as long as the supply lasts. There are not many left.

R. L. Taylor, Chairman of the Board of Directors, are having the grip.

If each National member would work to get new members as our recent candidate for president (Mr. Thomas Chantry) has done, we would number 5000 by the close of the honey harvest. Why not do so?

If our members who produce extracted honey will follow the advice given in Information Bulletin No. 15 there will be a great demand for honey, with hopes of better prices next fall. The bulletin contains the following on this subject:

### GREAT DEMAND FOR HONEY.

"I have devoted much time to discover why so many complain of no market for their honey. I have asked fifteen wholesale dealers why honey sales were slow when other foods found ready sale at high prices. I also asked bee-keepers who buy tons of honey besides their own for bottling, and also asked many who used to be extensive honey-eaters why they have dropped it from their daily food. Almost every one replies with this answer:

"Good well-ripened honey, sealed by the bees and matured in the hives, is always in demand at fair prices; but this thin stuff, extracted before it is ready, before it is well ripened—that will sour—that never has either flavor or body—that is what spoils the market for honey."

"Through the Information Bureau I have had sent me many offers of honey to sell. For several such lots I found sales, and later received word from the purchasers that the thin honey had no body or flavor, except souring. If every member of the National Association will promise me that *all of his honey will be ripe, capped-over honey* before it leaves the hives, he will have a market which he can never supply. Our Association can never brand the honey of its members until this is done."

By the time the members of the National get their honey ready for market this year I hope to be able to have new patterns of honey-labels for their special use.

On the evening of March 31, as General Manager N. E. France, with his wife, was mailing the last buggy-load of Bee-keepers' Legal Rights, they met with serious injuries by another team running into their buggy, upsetting it and causing a runaway.

Platteville, Wis.

N. E. FRANCE.

### A MODIFIED ALEXANDER PLAN FOR MAKING INCREASE.

The main honey-flow, which is from crimson clover, comes very early in this locality, beginning the last of April and extending until late in May. Our swarming is in March and April. I prefer to have my bees all in one apiary, but am compelled to divide them into four yards in order to find a good bee-range by actual test.

To head off swarming and to secure increase at the same time, I wish to try a combination of the Alexander and brush-swarming plans. When a colony makes preparations for swarming I intend to prepare a hive-body on the old stand, as suggested by Mr. Alexander, and put a queen-excluder over

it. The old hive-body I will set at one side, then brush all the bees before the new hive on the old stand; and when they have all gone in, place the old hive-body over the excluder long enough so that the bees will care for the brood. I will then remove the old body and set it at the side of the old stand, with the entrance turned the other way. In 21 days I can find the new queen in the old hive, cage her, and brush nearly all the bees in front of the new hive on the old stand, then move the old hive containing the new queen and her few bees to a new place as a nucleus, and finally release the queen.

By this plan, nearly all the strength of both hives will be given to the colony on the old stand in time for the clover flow. This will give the new queen with her nucleus until July to build up in time for the sourwood flow.

Will this work all right, or should I follow the ordinary plan of brush swarming? My bees, being nearly all hybrids, are very cross, and boil over when I open the hives. I am a poor hand at finding a queen.

Biltmore, N. C.

W. N. RANDOLPH.

"[The plan as proposed above will be perfectly feasible; indeed, if we are not very much mistaken, Mr. Alexander himself suggested this modification in one of his articles. The shaken-swarm plan can be varied materially to suit local conditions and certain plans that the apiarist may have in view. If he does not desire increase, then he can put the second drive of bees in with the first after the brood has all hatched out. If he desires increase, then he should, of course, move the parent hive to some other location. By your plan you secure increase, and at the same time give all the brood, after it hatches out, to the first drive.—ED.]

### BLACKS AND HYBRIDS SWARM LESS THAN ITALIANS.

I must add my complaint to that of Mr. W. C. Mollet, page 79, as to the excessive swarming of the Italians. My bees are in ten-frame hives. I always use baits in sections, and give the entrance an inch or so by the width of the hive in hot weather. I have had Italians of two different strains—southern-bred and red clover, and found the same thing in both cases—a mania to swarm. They begin before there is honey enough to go into the supers, and keep it up. Last season I undertook to prevent swarming entirely by removing queen-cells, but more than half swarmed in spite of me. A cell overlooked or a day's delay, and out they would come. Most of the bees in the neighborhood are dark hybrids, with perhaps a few pure blacks. The record for most honey per hive, so far as I know, is held by a colony of dark hybrids which has swarmed not at all in seven years, and has only a  $\frac{3}{8}$  x 8-inch entrance all the year round. Others, with similar hives and bees, have had very little swarming, while a neighbor who never got supers put on any of his had only a moderate amount of it. As a new swarm usually makes little or no honey here, and a hive which has swarmed once not much, this is quite an item. By putting back swarms and by careful attention I have been able to get a greater average per hive than others; but individually they have been outdone by those having little or no Italian blood. So far as I know, the experience of others in these parts has been the same. I suggest that, in this country as in Europe, there are places where the blacks are better than the Italians.

Concerning whitewood (poplar) honey, it is the best we know anything about here; but we get only enough of it to make us hungry nowadays.

McConnellsville, O., Feb. 10. H. D. TENNENT.

[See Mr. Macdonald's article, p. 296.—ED.]

### HONEY-DEW ALL RIGHT FOR EATING.

Is it not a fact that, when the honey-bee comes along and gathers this excretion into its honey-sac and then empties it into the cell in the comb, a change takes place, and that this excretion becomes honey-dew honey? and, through this change, is not all waste matter eliminated? If this is established, to what end is such discussion? In the hands of an ignorant press and certain competitive corporations it can work a good deal of harm to those who produce good honey as well as those who produce bad.

Calabasas, Cal., March 26. S. K. HEDSTROM.

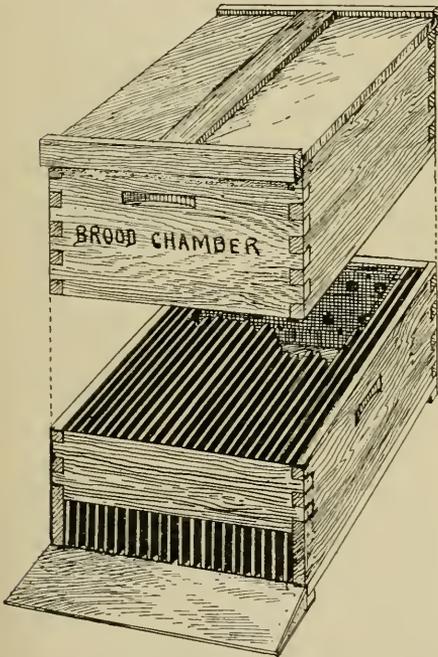

[An $\frac{1}{2}$  saccharine matter which the bees may gather is changed chemically, either just before or just after it is stored in the comb; but many of the original characteristics of the product will be the

same. For example, nectar from the onion-plant, when "inverted" by the bees into honey, will still have the onion flavor. Honey-dew, when inverted into honey-dew honey, will still have the flavor it had in the first place, although the flavor in both cases has been modified—that is, mellowed. An excretion is, to a great extent, a waste product. It has served its purpose of nourishment in its passage through the alimentary canal, and, through the process, has lost to a very great degree its power to sustain life; but honey-dew, while an excretion of a plant-louse, is a food for other insects, ants, and bees. As it is rich in hydro-carbon (sugar), the amount of waste, relatively speaking, for the bee is probably very small. Honey-dew, even though it be an excretion, can not, therefore, be regarded as an ordinary excrement. The alimentary canal of the plant-louse is probably as clean as the honey-stomach of the bee. There is no reason why a honey-dew of good flavor should not be as clean and wholesome as most honeys. We should not class honey-dew honey alongside of ordinary excreta.—Ed.]

SLATTED CLUSTERING-SPACE UNDER THE BROOD-CHAMBER TO PREVENT SWARMING.

Working along the lines as practiced by Dr. Miller in giving ventilation for swarm control I made a "contraption" that worked very successfully when placed under the brood-chamber of my worst colony of last year; in fact, it was the only colony this year that did not swarm.

I made a box of the same dimensions as a super, and same depth. The front I cut away half way up, making a large entrance. In the back I bored a number of half-inch holes extending across the box, and over these I tacked wire screen on the inside.

I filled this box or frame with partitions a bee-space apart. The partitions were made from old store boxes of about 1/4-inch stuff, but would have given more room and ventilation if something like thin fences had been used.

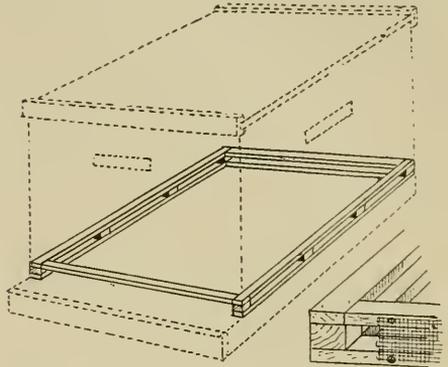

This contrivance gives plenty of clustering-space below the frames, a good current of air from the large entrance in front to the half-inch holes in the back. The objection I find to the blocks at the corners is that the manipulator is in the way of the flying bees if they can enter from all sides.

Nazareth, Pa., Aug. 23. GEO. H. BEDFORD.  
[It will be seen that Mr. Bedford has gone a step further than Mr. Junge, p. 295, in that his outer en-

trance is made very large—much larger than the average full-sized hive-entrance, and it seems as though this might be a desirable feature.—Ed.]

A FRAME TO PROVIDE EXTRA BOTTOM VENTILATION.

I have noticed the method of ventilating hives by placing inch blocks below the brood-chamber so as to have a space all around; but robbers or even mice could get in so large a space. To overcome this difficulty I propose the scheme as illustrated. After a

frame is made according to this drawing it will raise the hive-body one inch above the bottom-board with only a half-inch space. To stop the robbing we use a piece of wire cloth one inch wide, and long enough to go around the two sides and back of the frame, tacked on the outside. If four or five supers were tiered up it might be advisable to use one of these between supers. Of course, this must be tried before it can be recommended.

Washington, D. C. F. W. H. WEISHAUP.

ALLEY TRAPS IN OUT-APIARIES.

I should like to see reports on the use of Alley queen and drone traps in out-apiaries that are run for comb honey. Are they a success or failure in holding swarms until the arrival of the apiarist in, say, two or three days? Do these traps permit of sufficient ventilation during the swarming season?

When bees are allowed to swarm naturally and are then shaken, I find that much better results are secured. I had several cases of swarms issuing naturally; but as the queen could not fly, the bees returned to the parent hive. I then proceeded as in the shaken-swarm plan, and had splendid results. I have 200 colonies in outyards, and find that in some years all plans fail except natural swarming.

New Milford, Pa. F. W. DEAN.

[The Alley trap will hold swarms for two or three days; but as a rule it is far better to take care of a swarm within a few hours after it has issued. But the question may be asked, "How can we know that a swarm has gone forth?" Look carefully over the traps; and if a bunch of bees is found upstairs in any of them the presumption is that there is a queen there. The colony should be immediately shaken, and treated as a shook swarm.

When practicing shaking, care should be taken to do the work just before the colony is about to swarm. The presence of swarming-cells, and the disposition on the part of the colony to loaf, will show that it ought to be shaken. There is no earthly use in shaking the colony if it shows no swarming indications. In your case you can save a little trouble if you shake just before the swarm issues instead of doing it afterward.—Ed.]

THE POSITION OF BAIT SECTIONS.

My experience with bait sections has been that the bait should always be in the back end of the super, and on the side where the sun shines most during the day, as that is always where my bees start to work first when no baits are given, as the weather is cool in early summer. Bees work where it is warmer so they can make wax more easily.

Canon City, Col., Oct. 22. V. P. CUTLER.

## TWO SIMPLE METHODS FOR MAKING INCREASE.

In the *American Bee Journal* for last year, p. 275, a method of swarming bees is given. Is it necessary to have queen-cells in the sections when transferring from hive A to hive B, or do the bees make this queen-cell after the combs are transferred? It is not clear to me where the queen-cells come from in the queenless hive.

South Norwalk, Ct.

H. BEAUPAIN.

[Dr. Miller replies:]

To make it intelligible to others I give the plan: Take from the hive to be divided half its combs with the adhering bees. Put them in an empty hive and fill up each hive with frames filled with foundation and leave the two hives standing side by side. A week to ten days later there will be in one hive eggs and brood in all stages. The other hive will have only sealed brood and perhaps some large grubs. Move the latter hive to a new stand ten feet or more distant. The bees will do the rest.

This is not given as a best plan, but as one of the very simplest for a beginner. To make a more nearly equal division, swap the four frames of foundation in the queenless hive for four frames of brood of the other hive at the time when the queenless hive is moved to its new stand.

Answering H. B.'s question, the bees in the queenless part start queen-cells as soon as they are made queenless, and no queen-cells need be given them.

To make the plan still simpler (although not so good), merely make the division as directed, without any further change in seven to ten days.

The objection to all the foregoing is that you are not sure of the best kind of queen. Here is a plan which will give a good queen, although the plan is not quite so simple, because you must find the queen: Take two frames of brood with adhering bees, and put them together with the queen in an empty hive on a new stand. That leaves on the old stand all the field force and nearly all the young bees—everything in the very best shape to rear a good queen. In ten days let the hives swap places. That's all. You now have two good colonies. The one on the old stand with the queen and the field force will do good work at surplus. If you want it to do still better, brush (don't shake or you will kill the queen-cells) the bees from half the combs of the queenless part into the queenright part at the time you return the queen to the old stand.

Marengo, Ill.

C. C. MILLER.

## PREPARING BEES FOR SHIPMENT.

I am going to ship some bees by express late in April or early in May in eight and eleven frame hives. Some hives will have to be transferred to another railroad, and thus may be longer on the way. My bees were put out March 23, and were in good condition. I protected them with building-paper.

1. Will a rim on top of the hive to tack the wire screen to be too shallow if it is  $\frac{3}{4}$  thick, or should it be more? I have strips cut  $\frac{3}{4}$  thick.

2. What distance above this wire screen should I fix the cover for cool or warm weather?

3. What kind of directions should I place on the hive to insure careful handling by railway officials?

4. How long can bees be confined this way without much loss?

Giroux, Man., Can.

C. LANGILL.

[1. A rim such as you describe will be deep enough for this time of year. In hot weather we would advise not less than two inches deep.

2. One or two inches—preferably two.

3. We usually put on the words "Live bees. Keep out of the sun. Handle with care." The fact that the bees are "alive" insures careful handling on the part of the railroad people.

4. This depends upon the time of year, and how the bees are put up. When wire cloth is supplied top and bottom, and the bees given water, they can go a couple of weeks; but the water should be given quite often. If they seem to be suffering from want of air, the wire screens should be sprinkled with water to cool them off. This will drive them back from the wire cloth and cool them off. It is usually desirable to get bees through to destination as soon as possible. When properly put up they will go through without any water in good shape if not on the journey longer than four or five days.

A very important requisite is to see that there is sufficient ventilation for the size of the colony. Do not try to put a very powerful colony down into one hive-body. If it is very strong, put on a half-depth

super, then a wire screen. There should also be screen for the bottom, and below the screen should be secured the bottom-board so that there may be a clearance of a couple of inches. In the spring months the screen on top is usually sufficient.—ED.]

## SHOULD THE EXCLUDER BE USED?

In studying Doolittle's plan for the production of comb honey I am a little puzzled to understand the treatment in chapters 3 and 4. After the bees are shaken into the prepared hive and the super is to be placed thereon, is the queen-excluder recommended, or is it abandoned? He has removed the excluder that was used between the hive and prepared hive in bloom time.

Silver City, N. M., Jan. 27. MRS. O. C. HINMAN.

[This was referred to Mr. Doolittle, who replies:]

When the ten-frame Langstroth hive is used, there is no need of a queen-excluder. Often the bees are shaken into the prepared hive, for with so large a brood-chamber the queen is not inclined to put brood in the sections. With an eight-frame Langstroth hive, or a small sectional brood-chamber, it is well to use the excluder as a precaution against brood in the sections.

Borodino, N. Y., April 11.

G. M. DOOLITTLE.

## WILL PAPER INSTEAD OF CANDY DO IN AN INTRODUCING-CAGE?

What is the best method to introduce queens to a colony that has swarmed—that is, when I move the old hive to a new location, and in the morning wish to introduce a laying queen? Is it necessary to have candy in the cage, or would it do to fill up the hole with fibrous paper?

R. N. KING.

Wing, Ark., Feb. 18.

[The simplest and best way for the average beginner to introduce a queen is to use an ordinary introducing-cage having in one end a plug of candy which the bees eat out in from 12 to 36 hours. When the candy is removed the queen is released, and by that time will have acquired the scent of the colony. A plug of soft fibrous paper will not answer; but we frequently put a thin piece of pasteboard over the plug of candy to delay the entrance of the bees into the cage. This paper must not cover entirely the candy, as otherwise the bees will not eat it away. When properly put on, the pasteboard and candy will delay the bees' access to the queen from 24 to 48 hours. Without the pasteboard she may be released anywhere from 12 to 24 hours. This is too soon in many cases.—ED.]

## THE SCHOLL HIVE NUMBER.

Louis H. Scholl, page 87, 1908, gives his method of numbering hives, and invites bee-keepers to try the same and report. I have tried the plan for the last two seasons, and find it the most convenient I ever saw. The cost for my numbers up to 50 is less than 25 cts., and they will last for years. With these numbers the work of keeping a record of a colony is reduced to almost nothing. A. A. AUGENSTEIN, Dakota, Ill., Feb. 16.

## SPRAYING IN BLOOM DESTRUCTIVE TO BEES.

I should like to have some information about spraying with poison while the trees are in full bloom. Will it not spoil the honey? There are lots of bees in our place. Is there any protection?

Hockingport, O., April 5.

A. B. CHUTE.

[Bees will soon be killed in the vicinity where the Bordeaux mixtures are applied to the trees while they are in bloom. The experiment stations and practically all authorities now say that trees should be sprayed just before they come into bloom and about a week after the petals fall. There is no advantage—indeed, it is a great disadvantage to the fruit-grower—in spraying while the trees are in flower. See the statement by Mr. Waugh, on page 243. He is probably the best authority, from the standpoint of fruit-growers, in the United States.

There is no law in Ohio to prevent the spraying of trees while in bloom. The only thing you can do is to send the fruit-growers the April 1st and 15th issues of this journal. Secure a copy of Waugh's book, "The American Apple Orchard," and refer them to chapter 11. These ignorant fruit-growers should be posted.—ED.]

## Our Homes

By A. I. Root

He that hath no rule over his own spirit is like a city that is broken down, and without walls.—  
PROV. 26: 28.

Two weeks have passed since I told you Mrs. Root and I were dispensing with suppers; and, may the Lord be praised, we shall probably go without suppers the rest of our lives. Our lives will probably be not only longer, but of more value to ourselves and all around us. The idea is humiliating, I confess, but I am now forced to conclude that I have for about 50 years been to an infinite amount of trouble to take more nourishing (and expensive) food into my system than was needed or good for me. For a time I felt hungry about my usual meal time, and occasionally about bedtime I say to Mrs. Root, "Sue, I would willingly give half a dollar for a supper of beefsteak and baked potatoes if I were sure it would be good for me;" but instead of the supper I just went to bed, and when I awoke at just about daylight I didn't feel any hunger at all, and there was no bad taste in my mouth as there has been for so many years on first arising. Now pardon me if I speak plainly in regard to a matter that is likely to trouble elderly people more or less. For years past I have had troubled dreams, and distress more or less, unless I went one or more times to the water-closet. Terry has many times spoken of this, and suggested a remedy. Well, almost as soon as I gave up eating any thing after the noonday meal I began to sleep quietly and peacefully until morning. I now eat almost what I please at dinner time, and as much as I please, and a great lot of fruit (mulberries just now) after dinner. But even if I should occasionally feel a little unpleasantly full for an hour or two, before bed time every thing in the region of digestion is quiet and tranquil. Let me say *again*, that I feel ashamed to admit that I, through stupidity, have been all these years eating suppers I did not need, and would have been better off—yes, *far better off* without. My dear brother and sister, just think of the time you might have for pleasant and profitable visiting if there were no *everlasting supper* in the way. "Hail to the brightness of Zion's glad morning" when all men and women (who love the Lord Jesus Christ) shall consent to use the time heretofore spent in getting supper (and washing the dishes), for spreading the gospel or engaging in any thing that will benefit themselves and their fellow-men.

I am going to close this Home paper (penned hastily just before starting to my northern home), with a letter from a bright *young* friend who is just beginning to hear the "emancipation (from three meals a day) proclamation."

Mr. A. I. Root:—Yes, I was "listening" in the March 15th number of GLEANINGS when you were talking of Mr. Terry and his work for better and more sensible living. And I am one of the younger ones too—just passed my first quarter-century.

For several years I have been interested in hygienic living, especially in eating, but never put very much of it into practice, partly because I did not feel the necessity, and partly because no one around me made a systematic study of nutrition. I was always troubled more or less with a bad taste in the mouth on getting up in the morning. The thought came to me finally that it was more important to keep the interior of the body clean and healthy than the outside, for the membranes are much more sensitive; and when any thing gets wrong inside it is much harder to fix than a bruise on the arm or a corn on one's toe. Is it not true that, if we kept the exterior of our bodies as carelessly as many do their digestive tracts, we should be very offensive creatures indeed?

Fletcher's method of eating and living appealed to me in several ways. First, I wanted more time for reading and studying, evenings, so I began eating two meals a day and "Fletcherizing" more or less.

It is surprising how few of one's good ideas are carried out. I have put enough of them into operation, however, to be benefited very materially. I found that, by eating foods that combine well, and "chewing the stuffing" out of everything that goes into the mouth, six or seven hours' sleep now does where I used to require eight or nine.

Then there is a substantial saving, too. I am living on from two and a half to three dollars a week, and get my meals at restaurants mostly. My friends here pay from five to six dollars a week, and have to sleep two hours a day more than I do. It was not so very long ago that I required more myself.

But I have a very hard time getting just what I should have in a restaurant. The idea came that one could buy food such as the Battle Creek Sanitarium people put out, and, with fruits and nuts, have a diet that would supply all the elements needed to nourish the body, and the space needed to keep this food need not be large. So I tried it after getting some advice from the manager of the Sanitarium Food Store here in Denver. My food occupies no more space than my collars and ties, and my supper or lunch to-night consisted of several wheat and graham crackers, a few of Christian's honey wafers, a handful of shelled peanuts (raw), some honey, and then two good-sized apples. I did not make as much litter as a man does in smoking a cigar; had not a single dish to wash, no table-cloth to brush off or clear of dishes, and I do have a very pronounced feeling that it is sensible. One can not help becoming enthusiastic when he realizes what a small amount of energy is needed to supply the physical needs of the body, and how much more he has for work.

The Colorado Sanitarium, a branch of the Battle Creek institution, manufacture the same line of goods as are made in the East, and I get the goods at their store here in Denver.\* I enclose a little pamphlet on foods that tells some of the reasons for adopting this diet. No one teaching in regard to diet will absolutely suit every case; but the main thing is to study and experiment till the best system of nutrition is found. I consider my body a sort of garden that it is my privilege to cultivate to the utmost and bring forth to maturity the choicest of fruits, mental and physical.

You may rest assured that a goodly number of GLEANINGS readers digest your Home talks, for I have a chance to visit with a good many over this State, and they nearly all mention your department when bee-papers are spoken of.

Hoping to see many more of your Home papers I am with you for a century run.

Denver, Col., April 4.

WESLEY FOSTER.

"There are three very bright suggestions in the above. First, "It is even *more* important that we keep the interior of the body clean than the outside;" second, "My food occupies no more space than my collars and ties;" no table-cloth or dishes.

\*Address for valuable pamphlet and price list. Colorado Sanitarium Food Co., Boulder, Colorado. Denver Branch, 1515 Stout St., Denver, Col.—A. I. R.

Thirdly, "No one teaching in regard to diet will absolutely suit every case." "Our bodies are a sort of garden," etc.

Later.—To-day, April 23, we are back once more in our Ohio home. During our trip, which occupied the greater part of three days, we carefully followed our diet of two meals a day, eating nothing after our dinner at noon.\* As we reached Medina just about supper-time, each one of our five children urged us to sit down to supper; and I shall have to confess that the smoking viands were quite a temptation to us to break our pledge; and after our long and in some respects tiresome trip, the temptation was very great to have one more good square meal between five and six in the afternoon. But Mrs. Root and I both decided that we would not break in upon the new regime that has given us so much satisfaction. It requires some self-command and self-sacrifice, and "ruling of one's own spirit," and I am sure we both felt better than if we had partaken of food. The next morning I felt well rested, and not particularly hungry. And this whole matter explains fully what I have been trying to teach for many years—that in these lives God has given us to live we are to let *duty* rule, and not inclination. Our constant motto should be what I *ought* to do and not what I *want* to do—that is, our lower appetites and animal nature should be constantly subservient to reason and good common sense.

Now I will add in closing that I still have my apples in the evening—that is, a few good ripe mellow apples, so you will not think I do not practice what I preach. I have tried both ways, with and without the apples, and I am satisfied that the fruit alone does not tax my digestive apparatus in any way so as to be a detriment. Mrs. Root does not care for the apples in the evening.

## Poultry Department

By A. I. Root

### GETTING RICH WITH CHICKENS: THE OTHER SIDE OF THE MATTER.

*Mr. A. I. Root.*—I notice that you have been kind enough to express hearty approbation of Mr. Boyer's write-up of the Corning egg-farm. You have also even more heartily approved Milo Hastings' book, "The Dollar Hen," as well as the Prairie State Incubator Co's catalog. It is a long distance between the conservative statements in the latter books and the title of the Corning egg-book.

I have been waiting for criticism of the Corning egg-book; but I have not yet read any thing of that kind. I was hoping that, with your penchant for showing up the poultry fakes, you would have read this book carefully enough to discover the delusive mode of reasoning employed to obtain the above-mentioned title. The statement of "\$6.41 per hen

\* I have already talked about the saving in time and money by having only two meals. If this is true in the home, how much more is it true when traveling! Three meals a day taken in the dining-car is rather expensive business, as you know if you have tried it. Well, you not only cut off a third of the expense, but you will find you can stand the wear and tear of travel very much better.

per year" will, if allowed to go unchallenged, cause a great many would-be poultry-farmers to embark in the poultry business who never would have gone into it had the statement been conservative. This letter is written to try to save those who may risk their small savings in the "Corning method" (?).

In the first place, look at the admission that the Cornings have spent three years and over \$20,000 on this egg-farm—a considerable part of one's life, and a good-sized fortune for the ordinary man.

In obtaining the net profit per hen, no mention is made of the interest on investment, insurance, up-keep due to depreciation, etc. Let us estimate what this amounts to.

INVESTMENT—			
12 acres of land at \$500	- - -		\$6000 00
1 Homestead	- - -		4000 00
1 plant, including implements, automobile, horses, etc.,	- - -		30000 00
INSURANCE—			
Plant at rate of 50 cts. per \$100	- - -		\$150 00
House, \$2500 at 25 cts. per \$100	- - -		6 25
UP-KEEP—			
15% of \$30,000 (see Dollar Hen, p. 71)	- - -		\$4500 00
INTEREST—			
8% of \$30,000	- - -		\$2400 00
6% of \$10,000	- - -		600 00

Note that the homestead is charged against the hens, because just that amount is tied up and can not be used in the egg business.

Accepting the figures on page 13 of the Corning egg-book relating to revenue and expenditures at their face values, we shall have for revenue \$15,714.84. To the expenditure of \$3194.03 we will add insurance, \$156.25; up-keep, \$4500; interest, \$3000, or a total of \$10,850.28. Subtracting this from the revenue we get \$4864.56, or the Cornings would have over \$2400 each for their labor per year, out of which they would have to pay their living expenses. Taking the above figures into account, the net profit per hen per year would be \$2.49—a figure much more reasonable than \$6.41.

Not wishing to throw any doubt on the figures as set down, and criticising only the methods of obtaining them, let us try to show what the average would-be poultry-farmer could expect. We learn that 23,316 dozen eggs were laid in ten months on the Corning farm. This number was obtained by multiplying the total number of hens (1953) by the average egg yield per hen for only ten months. A serious misstatement is made on p. 18, end of paragraph three of the Corning book—"Leghorns on Sunny Slope Farm last year averaged 143.25 (eggs) for ten months, at the rate of 171.9 a year." Suppose the hens laid no eggs for the remainder of the year, the yearly average would be about 120 eggs per hen year instead of 171.9. Probably 125 would be a fair estimate, as some hens would lay during the moulting season. What would this do to the Cornings' figures, if they kept their hens for 12 months after they began to lay, as most of us do? I do not see why it is not correct, when figuring on a yearly basis, to count in two months before pullets begin to lay. I should like to ask the Cornings if they would buy several thousand moulting hens (yearlings) and pay just one dollar apiece for them. Certainly 144 eggs per hen per year is not exceptional for a large flock of hens when the drones are eliminated by trap nests. The Cornings use no trap nests, and 125 eggs per hen per year is all they could expect by their method—see *Respectable Poultry Journal*, December, 1908, page 967, end of first paragraph of first column.

When it comes to the price received for eggs sold by the Cornings, it appears to me that they forgot to mention the cost of shipping, and also that only the best retail prices were averaged. No mention is made of the prices received from commission merchants, although it is admitted that eggs were sold to such (see middle of page 15, Corning book). No mention is made of the cost of selling, such as advertising, stationery, postage, printing, greasing the Stewarts' palm, etc. Such things as these would have to be paid for by the ordinary farmer. Note that the Cornings' letterhead reads that their eggs are "delivered daily by messenger," which ought to cost something when 20,000 dozen eggs are so delivered.

The average price paid for eggs by consumers in the United States during 1909 was 33 cents, and they were sold by the farmers at an average price of 22 cents per dozen. Milo Hastings has charted a price-curve on page 172 for the price of eggs during 1908.

The highest price is about 32 cents, and eggs were retailed in New York city for nearly double that amount during the early part of the winter. The average price received by F. B. Atherton in 1908 for eggs was 32½ cts. per dozen, from which was deducted express charges, commission, breakage, and return of empty cases. This amounts to about 5½ cts. per dozen, making a net average price of 27 cts. (see "Egg-farm that Pays \$1300 per Year," *Reliable Poultry Journal*, December, 1908).

I should like to ask the reader what price he thinks he can obtain for eggs when selling upward of 20,000 dozen per year.

The Cornings are credited with selling 1900 hens, although they are called pullets, for two dollars each, when sixteen months old. These hens were starting to moult, and could not be of much use for the next six months. The reason given for the high price received is that they were sold for breeding purposes. It is universally admitted that yearling hens make good breeders; but hens kept in confinement, and forced for eggs, have lost a great part of their vitality, and never can produce strong healthy chickens (see *Prairie State Incubator Catalog*, pages 5, 15, 24). The inexperienced (or otherwise) persons who purchase such birds for breeding purposes get "stung;" and whose reputation suffers in the end? Personally I should like to get two dollars each for yearling hens in large quantities, or even that amount for pullets a year younger. According to the advertisements that have come under my observation, the poultry-raisers are very glad to get two dollars apiece for their young surplus stock when sold singly, and are glad to accept \$1.25 to \$1.50 each when selling by the dozen. Even at that they do not advance their prices until December. If the would-be egg-farmer figures that he can get 75 cents per head for yearling hens (especially Leghorns) he will be high enough.

On page 21 the Cornings speak of their original and economical laying-houses. In the first place, houses just as good could be built for half the money. The only original principle employed is to build these houses so as to house one large flock. The objections to this kind of house are draughts and disease. In order to get out of the wind blowing through this house, the hens have to crowd back under the dropping-boards (see middle of page 36). Disease can be kept under only by eternal vigilance. The chief criticism I have to this house is the small amount of opening there is in front, especially as the hens are allowed only in the scratching-room in warm weather (see bottom of page 36). These houses are almost identical in size and shape with mine, an illustrated description of which was published in the *Reliable Poultry Journal* for January, 1909. Many poultrymen, including myself, use the dry method of feeding. The hens get a large feed at night, consisting of a quantity of the best commercial scratch feed and a varying quantity of cracked corn and oats scattered in the litter. At the after-dark inspection more grain is buried in the litter if deemed necessary. Water is given them every morning—hot in winter. At noon, sprouted oats and table-scraps are fed. A hopper containing dry mash is placed before the birds in the afternoon. Mash consists of corn meal, bran, middlings, red-dog, ground oats, beef scrap, cut clover, charcoal, etc. Hoppers containing grit, shell, and charcoal are placed before them all the time. The hens enjoy picking cinders out of the coal ashes that are spread upon the dropping-boards.

West Nutley, N. J., March 30. A. W. FLEMING.

Thanks, friend F., for your criticism of the Corning egg-book. I still think the book a valuable contribution to our recent poultry literature, even if it does give an extravagant idea in many respects. In fact, I think it very much superior to most of the books written to show up a particular system. In looking over the book hastily I was especially pleased with the footnotes from Boyer.

The *Farm Journal* folks may have something to say in regard to your criticisms of the book; and if so I shall be very glad to receive them, for God knows we want to give the great hard-working public the real

unvarnished truth in regard to the poultry business.

While on this subject I wish to say something more about the book I mentioned on page 167, March 1—"the Kellerstrass way of raising poultry"—the book that "one can read through in 35 minutes, but which took 36 years to write." In the very opening chapter of the book Mr. Kellerstrass says, "Remember, I have been a good many years writing this book, and it is all from actual experience—no hot-air dreams, but actual experience." I have before pointed out to you that a great part of this dollar book, with only 91 pages, is devoted to advertising extravagantly his eggs at \$2.00 apiece. Now, one of our poultry-journals has recently pointed out that this is not all of it. Another great part of the book is made up of directions for work during every month in the year, from January to December. When I read over these instructions it seemed to me they did not refer *particularly* to the "Kellerstrass way" nor to the Crystal White Orpington chickens. Well, this poultry-journal calls attention to the fact that nearly all of these instructions for each month in the year are *copied*, the greater part of them, word for word, from Park & Pollard's *Poultry Almanac*, Boston, Mass. This almanac (for the years 1907, 1908, 1909, and 1910) and the Kellerstrass book are before me. How does this condition of things correspond with the paragraph I have quoted about "no hot-air dreams but *actual experience*"? What explanation has Mr. Kellerstrass and his numerous friends (including many of the poultry-journals) to make about it?

## High-pressure Gardening

By A. I. ROOT

### TESTING SEED CORN IN OUR SCHOOLS.

The Department of Agriculture, Washington, has just done a wonderfully wise thing in preparing a pamphlet, dated April 9, 1910, for use in our schools, and especially our country schools, instructing the teachers and children how to test seed corn before it is planted in the field. I can not think of any thing more valuable in the education of a child than to interest him in seed germination. This method, if followed out, would not only add thousands of dollars, but perhaps millions, to the income of the farmers of our nation. Last, but not least, it would tend to put the parents and teachers in touch with each other better than almost any thing else; and it certainly should give the parents confidence in regard to the value of the schools by getting the children to be on hand promptly on every school day. Apply to the Department of Agriculture, Washington, D. C., and ask for Circular 96, entitled "How to Test Seed Corn in the Schools."

The plan is about the same as I have

given in GLEANINGS every spring for three or four years. It takes about fifteen ears of good size to plant an acre. Select the best ears you can find. Place them where they will not be disturbed, in rows of ten ears each. Then get a shallow box, say 1½ feet wide and 2 feet long. Fill it with sand or good garden soil, and then with tacks and strings lay it out in squares about 1½ inches on each side. Have as many squares as you have ears of corn. Our plan is to lay a piece of two-inch-mesh poultry-netting over the box. Fasten it down with tacks, and then take five grains of corn from each ear and plant them in the meshes of the poultry-netting. Have your box numbered across one end and across one side, and have it so arranged that, when any square does not show five good strong corn-plants, the ear from which these five kernels were taken may be discarded. In this way, when you come to plant you are pretty sure to have a good strong plant from each kernel of corn. The average schoolchild, with a little instruction from the teacher, will soon learn to do the work, and will greatly enjoy it.

May the Lord be praised for this new and wonderful scheme for getting our American schools in touch, not only with high-pressure gardening, but high-pressure agriculture in general.

#### SOIL SUITABLE FOR SWEET CLOVER.

I have inquiries from readers of the *Rural New-Yorker* in regard to the seeding of sweet clover and the character of soil best suited to it. Sweet clover will grow on any soil that is not water-logged if it contains sufficient moisture to sprout the seed. On very thin and worn soils the growth is small compared with that on fertile soils. We use sweet clover to build up thin and much depleted soils—fields that have become useless as pasture—those filled with washes and gullies. These fields generally have a growth of small bushes or briars, where they have been lying idle for several years. These are cut and tramped into the ruts. The tops of the little ridges are dug off and raked into the ruts, which help to hold the briars and bushes in place until they are converted into humus. If the washes and gullies are not too deep the seed is harrowed in with a double A harrow; otherwise the seed is sown early in the spring, just as soon as the soil can be stirred, and about half a bushel of spring oats sown with it. The amount of seed to be sown per acre on fields as described above is 15 or 20 lbs.; on soil that is reasonably fertile, where sown for hay or pasture, 25 to 30 lbs. per acre. Where sown to produce seed, the soil should be reasonably fertile and 15 lbs. of seed per acre sown broadcast, and harrowed in. Sow as early in the spring as the soil can be stirred. For fall seeding, prepare a good seed-bed and sow the seed in October.

Sweet clover for hay should be cut just as the first blossoms appear. If left standing longer the stems become woody, and a great many of the leaves fall off when cured. Great care should be exercised to prevent the hay sun-burning, as this will destroy the palatableness and its nutritive properties. There is no better way to fit a piece of ground for alfalfa than to seed to sweet clover, cut off a crop of hay the first season, and plow under the second season when the clover is about a foot tall; then cultivate with drag and harrow until the first of September, then seed to alfalfa. The sweet clover improves the soil and inoculates it with the nitrogen-gathering bacteria which are so necessary to the existence of alfalfa. When seeding for hay I would not use any nurse crop; and do not cut too close to the ground the first time. Leave five or six inches of stubble to protect the crown and roots until a new growth is made. If permitted to go to seed the second season, and the seed to ripen, it will reseed itself. The sweet-clover plant lives but two years. It dies at the end of the second season, and its large fleshy

roots decay rapidly, admitting the air deep into the subsoil.

Warsaw, Ky.

J. W. G.

—*Rural New-Yorker*.

## Temperance

When I gave place to "Who are the guilty ones?" on p. 96, Feb. 1, I was aware it had appeared in print a good many times, and also that it might not all have occurred exactly as given there; but since then a clipping has been sent me of something that *has occurred* quite recently, very much like it. May God be praised that even judges are beginning to wake up and call things by their right names. Here is the clipping:

#### THE SALOON CONVICTED; THE BOYS HANGED.

In pronouncing the death sentence on two boy murderers at Owatonna, Minn., Judge Buckman delivered this philippic against the saloon:

"Every community can well ask if it is not equally guilty with its sister city in not making a vigorous effort to remove the snares which lie in waiting for the young in almost every town in the Union. These boys can not have been brought to perpetrate such a crime through the influence of heredity. There is nothing to show it. It must be charged, if it be true that they are guilty, to their environment. Without any ill feeling toward the people of this community, I must say that they are *particeps criminis* in this tragedy, if the boys are guilty. The people have allowed the conditions which have brought these boys to such a pass. It is because the boys could procure of newsdealers such literature as debased their moral natures; because the police, knowing of the conditions existing in the rooms of these, permitted them to go on; because the saloon-keepers of the city were allowed to place on the lips of the young that which fires the brain and sears the soul. By imposing the death sentence the court will be striking at the effect, not the cause; and if the cause remains undisturbed, the result will be another such case as a righteous retribution upon those responsible."

#### HITTING THE NAIL SQUARELY ON THE HEAD.

The following, which I clip from the *Chicago Advance*, sums up the whole matter of "wet and dry" better than anything I know of. I wish it could be held up before the whole wide world, until every man, woman, and child has read it.

#### LET THEM MOVE.

The following appeared in the funny columns of the press recently:

"What are they moving the church for?"

"Well, stranger, I'm mayor of these diggin's, an' fer law enforcement. We've got an ordinance what says no saloon shall be nearer than 300 feet from a church. I give 'em three days to move the church."

This incident did not occur in Chicago, but the idea has been occurring every day since the anti-saloon campaign began. It is about all there is of the saloon side of the question. Wives have cried out in agony that the saloons were taking the husband's wages and robbing the children of bread. "Well, let the wives move out and the children stop eating." Mothers have said with bitter tears that saloons were ruining their sons. "Well, let the mothers forget their sons and stop their whining." Citizens have declared that saloons are the resort of thieves and the whole bad bum element. "Well, let the good citizens go to some other country, if they don't like it."

In a word, the saloons are against the welfare and the common good which all law and righteous government are intended to promote. "But let it all go—the saloon must stay."

How can the people of a county that has voted *wet* look a good man or woman full in the face after reading the above?

### MILLER'S PATENT AUTOMATIC SWARM-CATCHER.

ON the front cover of this issue we take pleasure in presenting a swarm-catcher that is absolutely automatic. We do not know whether it "works for nothing and boards itself," but we are inclined to think not. The inventor tells of it in this wise:

The illustration shows an experience I had in hiving a swarm of bees. I had had but little experience with bees, but had learned that, if I caught the queen, I could get the bees where I wanted them. I walked up from quite a distance down in the field with this swarm, and my wife took my picture. I like to be on friendly terms with the bees, but this was a little greater display of intimacy than I was expecting.

Denver, Col.

W. L. MILLER.

### NEW JERSEY GETS A FOUL-BROOD BILL PASSED, AND THEN THE GOVERNOR VETOES IT.

THE following letter, just received from the Secretary of the New Jersey Bee-keepers' Association, will explain:

The bee-keepers of New Jersey, through their State Association, succeeded in getting a foul-brood bill passed, with practically no opposition; but when it came before the Governor for his approval he vetoed it on April 12. We do not know his reasons, but understand he considered it too drastic.

Our bill was modeled after the one recommended by Dr. E. F. Phillips, and was considered a good one by all who saw it.

We think it was rather from a lack of understanding of the whole matter more than any thing else on the part of the Governor that he vetoed it. We spent all our efforts to get a bill on the assemblymen and senators, thinking the Governor would surely approve.

To say that we are highly disappointed is expressing it mildly. After working so hard to get a bill passed, and then have it stabbed by the Governor, was the least of our expectations. But then, there is no use in fretting. We shall simply have to stay sweet, and try again. I suppose we shall have to frame a bill to meet the Governor's objections, and try again next winter. This is our individual opinion, and will have to be approved by the association. In the mean time we should like to have more bee-keepers join the association. Dues are 50 cts. a year. We know some bee-keepers who have held aloof from the association, thinking we could never get a bill passed. The stronger our association, the stronger the show we can make next winter.

Pittstown, N. J.

ALBERT G. HANN, Sec.

The New Jersey bee-keepers have been working long and hard to get a foul-brood bill passed. There was most urgent need of it, and it is unfortunate that the New Jersey bee-keepers did not see the very great importance of informing the Governor of

its importance. Gov. Folk, of Missouri, vetoed a foul-brood bill after it had passed both houses, simply because he did not know any thing about the bee-keeping industry nor the dangers that were threatening it. These two cases ought to be a lesson to other States that are working strenuously to get foul-brood laws on their statute-books.

### "SELLING THE HONEY CROP TO THE BEST ADVANTAGE."

UNDER the above caption, Mr. Hutchinson, of the *Bee-keeper's Review*, in his issue for May, has quite an extended editorial. In the first two paragraphs he says:

"Did you ever stop to think that you spend all of your season producing your crop of honey, and then sell it in about fifteen minutes?" I came across the foregoing sentence in a circular just sent out by the energetic, enterprising secretary of our Michigan State Bee-keepers' Association. It is true that we bend every energy to the successful wintering of our bees; we make chaff hives, or protect the bees with some kind of packing, or we put them in the cellar and then watch the temperature as a mother watches her sleeping child; we feed the bees in the spring if they need it; we coax them into the supers by means of "bait" sections; we lift and sweat, and suffer stings; and, finally, crate up our beautiful product with loving care, and then, as Bro. Tyrrell says, some of us sell it in about fifteen minutes.

The indifference exhibited by some producers in disposing of their crop is certainly exasperating. We can not all peddle our honey; we can not all sell it to retailers; we can not all build up a mail-order trade. Some of us must sell to wholesale dealers, or consign to commission men; but in any case there is no excuse for the lack of interest, the utter indifference, the "I'll-take-whatever-you'll-give-me" spirit.

Further on he says, "In other lines of business, production is looked upon as only half the problem." . . . "The selling end has been shamefully neglected." . . . "It is quite likely that many men are now following the plan that is best for them; but it is equally evident that thousands of men are not—men who might materially increase the revenue from their crops by some change in their plan of selling." . . . "Not every producer can become a successful retail salesman." . . . "It is safe to admit that men who are now retailing their honey might find it much more profitable to increase their production until it reached the carload stage, abandon the retail trade, and turn their whole attention to production." . . . "Selling should be only a part of a plan that is the most perfect for some particular man and his environments. What I am pleading for is the proper recognition of the importance of the selling factor."

It is probably true, as Mr. Hutchinson says, that bee-keepers have not been giving enough attention to the "selling factor."

We shall be glad to open our columns to a discussion of the same subject.

After all that is said and done, honey production is a business in itself. The art of selling at good prices is entirely another business. It is seldom that we find any one man sufficiently educated in the art of producing and selling both; and it therefore follows that the great majority of bee-keepers will have to depend on some one else to do their selling. While this is true, there are many bee-keepers who are doing a fine business during winter in selling their honey in small lots to the local retail trade.

One of the things we have been trying to hammer into the heads of bee-keepers is the fact that honey should be sold *early*. While it can be disposed of to advantage in August, September, October, and November, there is not much doing after the middle of December; and honey that has not already been sold during the holidays is apt to have a slow sale afterward at reduced prices. In view of the fact that white clover gives indications of furnishing a liberal yield this coming summer it would seem advisable, as Mr. Hutchinson says, to get the honey on the market as soon as possible. There are many bee-keepers who wait until it is "convenient" to take it off their hives. They then sell when *everybody else* is selling, and when prices have a tendency to drop. They thus get into the fiercest kind of competition. "It is the early bird that gets the worm." No honey sells like fresh *new* honey.

#### THE OHIO LEGISLATURE PASSES AN EXCELLENT FOUL-BROOD LAW.

SOON after we had gone to press with the last form of our previous issue, word was received that our foul-brood bill had passed both houses; we stopped the press and squeezed in a one-line notice. From the earlier reports we were fearful that the bill would not even be reported out of committee; but, thanks to the energetic action of Senator Patterson, the father of the bill, and Representative Woods, who had charge of the bill in the house, the bill was not only pulled out of committee in both houses, but it was put on the calendar, and passed. The bill is now before Governor Harmon for his approval. We have written him a strong letter urging his support, and so also has the secretary of the Ohio State Board of Bee-keepers, Mr. Henry Reddert, of Cincinnati. We have every reason to believe that he will attach his signature, and the bill become a law. The bill was drafted originally by Dr. E. F. Phillips, of the Bureau of Entomology, Washington, D. C., and then it was modified by the attorney-general to suit local conditions.

Senator F. N. Patterson and Hon. Frank Woods, both leaders of their respective houses, deserve the special thanks of the bee-keepers of this State for the prompt and energetic way in which they pushed the bill during the last day or two the Legislature was in session. We were very fortunate

in the selection of our men to handle the bill. Considering the dead lock between the two houses at the time, we were exceedingly fortunate.

In brief, the new law provides that the Ohio State Board of Agriculture shall establish a Division of Apiary Inspection in the Ohio Department of Agriculture, and shall also appoint a competent entomologist who shall be chief inspector of said division. In this case, the Board will undoubtedly appoint State Entomologist Shaw, who, of his own accord, when we were agitating the question of getting a better law, offered us every assistance in his power. It goes without saying, that Prof. Shaw, if appointed, will do his part.

Among other things, the law provides that the inspector or his assistants, when notified in writing, shall examine all reported apiaries where disease is supposed to reside. After the first inspection he shall make a second inspection ten days later. Under the law, no one will be allowed to sell or barter, without the consent of the inspector, any diseased bees or appliances. It is further provided that no person engaged in rearing queens for sale shall use honey for use in making bee candy for mailing-cages unless it has been boiled for at least thirty minutes; that all queen-rearing apiaries shall be inspected at least twice a year.

For this year, at least, the Entomologist will not have any special funds to pay salary and expenses of special bee-inspectors; but he has kindly consented to have his regular nursery inspectors take on the additional duty of inspecting bee-yards. Another year, when the Department of Agriculture makes up its new budget, funds will doubtless be provided to take care of an inspector or inspectors who can devote all their time to inspection work. For the present, at least, we must not make too heavy demands on the chief inspector. It was thought best to get the law passed now, in order that localities affected by the disease might have the police power of the State back of them. It is unnecessary to say that local bee-keepers will see to it that the nursery inspectors, when they do come around, will be supplied with all the technical information they may lack in properly carrying out the provisions of the law.

#### TEN-FRAME HIVES VS. EIGHT-FRAME; FALL OR SPRING FEEDING.

THE following letter, received from one of the veteran bee-keepers of New York, and a man who has been connected with the supply business for the last twenty-five years, is of such general interest that we are glad to place it before our readers.

*Mr. E. R. Root:*—I have just received GLEANINGS for April 15, and noticed, on p. 241, your editorial in regard to ten-frame hives. I wish to say that the editorial meets my views exactly. When I first began keeping bees I used the ten-frame hives and had good success right along. About the time Mr. Heddon got out his sectional hive I changed to the eight-frame regular Dovetailed hive, having about 130 colonies. My luck seemed to leave me; but I continued with the eight-frame for about ten years.

I then changed back to the ten-frame, and, presto! my luck returned. Since then I have had good success. My specialty was comb honey. A few bee-keepers ask my advice, and I always recommend the ten-frame, but tell them that sales are mostly for the eight-frame, and they can take their choice. I also note your footnote on p. 249 in regard to spring feeding. This I have advised for a long time, and in accordance with your idea. I sometimes feel that you and I would agree on the care of bees.

Syracuse, N. Y.

F. A. SALISBURY.

It is our opinion that the great majority of the eight-frame hives now in use among the old-time bee-keepers continue to be used because of the fact that they can not afford to change over to the ten-frame size. This is only another way of saying that many of these men, at least, would change over to the ten-frame hives if they were to start over again.

We are coming more and more to the conviction that the ten-frame hive will hold its own anywhere at any time. In late spring an eight-frame hive will often be jammed full of brood. To put on an extra story to accommodate the queen gives too much room. Two extra frames, as can be given with the ten-frame hive very nicely, accommodate the average good queen. From extended travel and observation, covering a period of fifteen or twenty years, we have been slowly coming to the conviction that the eight-frame hive is just a little too small, and that the ten-frame is about right. If it is necessary to have a reduced body capacity, better by far make the reduction on *vertical* than *horizontal* lines.

It is a great nuisance to the bee-supply houses and bee-keepers in general to have two kinds—that is, two widths of hives, for the same kind and depth of frame. Every supply house must carry a full assortment of the two sizes. Somebody must pay for this duplication, confusion, and expense, and, naturally enough, it comes out of the bee-keeper. We hope the time may speedily come when there will be only one width of cover and bottom-board, one width of super and one width of brood-nest, especially since the varying capacities of brood-nests to suit individual and local needs can easily be taken care of by increasing or diminishing the depth. A ten-frame-width shallow or deep brood-nest will fit any cover or bottom-board or super, and this is a matter of supreme importance. One can work shallow brood-chambers, medium shallow, standard full-depth Jumbo, or extra-deep Langstroth hive-bodies and supers in the same yard without any inconvenience; but he can not work satisfactorily two widths of hives in the same yard.

THE ENFORCEMENT OF THE NATIONAL  
PURE-FOOD LAW; HEADACHE CURES,  
AND SHORT WEIGHTS IN FOOD  
STUFFS.

The food and drug department of the United States Department of Agriculture is evidently going after the adulterators of foods and drugs, especially those who have misbranded. As some of their decisions

bear upon the honey business, directly or indirectly, it will be proper here to refer to a few of them. For instance, one company has plead guilty, and been fined for sending out maple-sugar syrup, as the syrup contained almost entirely cane syrup and only a very small amount of maple syrup. The bottles were labeled "Cane and Maple Sugar Syrup;" but the words "Cane and" were put in small letters, so as to be inconspicuous. As this is contrary to the provisions of the national pure-food law, the authorities decided that the packages were branded and labeled so as to deceive and mislead the purchaser thereof.

Another concern was fined for selling packages of preserves that were short in weight. The label stated, "This package contains one full pound." This statement was false and misleading, in that each of said packages contained less than one full pound; to wit, an average of 14.5 ounces.

The "O. K. Headache Cure," claiming to cure any kind of headache, and perfectly harmless, "was misbranded in that the containers failed to indicate to or advise the prospective purchaser or consumer of said preparation that it contained alcohol and acetanilide, the presence and quantity of which substances are required by law to be declared on the package containing the same, and which was further misbranded in the following particulars, that it was not a cure for headache, and it was not perfectly harmless, because acetanilide, a dangerous drug necessitating skill and caution in the administration thereof, was present in said preparation."

There is provision in the national pure-food law by which the use of false geographical names is prohibited. It seems there are concerns that were selling Rocky Ford muskmelons and Indian River oranges; but neither the canteloups nor the oranges came from the localities indicated. The law holds that these geographical names should be applied only to the product of the strict area of melons grown in the Rocky Ford district of Colorado and oranges in the Indian River district of Florida. In brief, Uncle Sam says, "All labels must make no misstatement, either as to weight or character of the substances used in the food or drugs. If any substance is dangerous to life or health, the exact quantity must be stated on the label."

By the way, why should any one buy patent-medicine headache cures? There are records of a number of deaths occurring because the cures contained some deadly drugs that stopped the heart action and caused death. Bee-keepers do not need to be cautioned against headache cures more than any one else; but they should thoroughly understand that, when a label specifies one pound or any definite quantity of honey, there should be exactly that amount. A can or bottle that weighs gross a pound, and contains net 14 ounces of honey, when labeled as containing a pound, is a violation of the national pure-food law.

## Stray Straws

By DR. C. C. MILLER, Marengo, Ill.

THE CENSUS man struck a rather bad year for bee-keepers, didn't he?

NECTAR contains 93.76 per cent of water; and honey, 20.6 per cent, according to German official investigation. — *Lpzg. Bztg.*, 42.

LUDWIG says, *Am. Bienenstand*, 73, that moldy combs in winter may be due to hives of fatty pine. That seems to favor Doolittle's idea that unpainted hives are better for wintering.

BABY NUCLEI swarm out, page 279, Dr. Kramer says, *Schweitz. Bztg.*, 178; take bottom off nucleus hive; set it over an empty one, and the baby will build and brood with no thought of swarming.

WESLEY FOSTER, I wonder if your section-dampener, p. 293, is as good as a fine stream of hot water from a fountain syringe. It does fair work on a whole package of sections, and splendid work on half that depth.

"WITH AN eight-frame Langstroth hive . . . it is well to use the excluder as a precaution against brood in the sections," p. 300. In this locality no excluder is used between eight-frame hive and sections.

SOME omit breakfast, some omit supper. I've tried both ways; don't know which is best, or whether it's better to eat three meals, and eat each meal in two. The thing is, don't eat too much, and chew, chew, chew.

THE PLAN outlined by Louis Scholl, page 246, selecting his best queens for his queen-yard and breeding from the best, will in a few years give him bigger crops. And the man with only 20 colonies can do something in the same line.

D. M. MACDONALD, why can't you stay in Scotland, where you belong, without stirring up trouble on this side, p. 296? I've troubles enough of my own with another descendant of Scotland who objects to my introducing fresh Italian blood to work out the black blood.

BEEN TRYING a pair of home-made gloves made of heavy woolen yarn. The bees fly at them furiously, and try to burrow in them. Knew that before—did you? Well, here's something perhaps you didn't know—at least I didn't—for all their bluster, never a bee really stings, never one! They pepper a wool hat with stings, why not the gloves?

Later.—Got stung three times in half a day on the identical spot inside of a finger. I think the glove was thinner there. But why don't they leave any stings on the back of the hands or fingers?

"SELLING patent-right territory" is bunched among objectionable things formerly advertised, page 241. What's wrong

about selling patent-right territory? [Nothing is inherently wrong with the *principle*; but years ago the *practice* was very much abused—so much so that it has practically gone out. But, say, doctor, why don't you answer this question? You lived in the days of patent-right selling, and are supposed to know more about it than the writer.—ED.]

PERIOD of bloom three or four weeks earlier than usual. Duchess apple 41 days earlier this year than last. But after a long spell of summer came snow and ice—thermometer 21°. Some trees were utterly denuded, same as in winter. Fruit is about all killed; but since thawing out, bees still work on apple-blossoms, which are black at heart. Bees stood it grandly; are now at least three weeks in advance of any previous year. April 29 honey shook as in the midst of a heavy clover flow.

REPLYING to my question, p. 244, you say, Mr. Editor, that foul-broody entrances and alighting-boards should be disinfected. Does that mean that the danger-line ends there, and that there's no need to disinfect further out? What about the millions of spores scattered all over the ground and on top of all the hives in the apiary? [Spores on the outside of the cover or on the ground would probably be killed outright by the action of the sun. Disinfection of the interior of the hive or entrance would, we think, be sufficient.—ED.]

THE BEDFORD anti-swarming device, page 299, ought to hinder swarming just as my bottom rack does, *provided* the entrance under the device is large enough. But placed in front of a hive as shown on page 295, I should expect it to increase swarming, just because it decreases ventilation. The Bedford device, p. 299, is O. K.; but instead of holes at the back end why not have it more open, same as front? The Weishaupt arrangement, p. 299, is only to keep out robbers and mice. But I never knew either robbers or mice to trouble a hive raised on blocks, and the arrangement shuts off half the ventilation. But don't forget, good friends all, that a 1/4-inch opening at the upper back end of the hive is as good as adding an inch at the bottom.

THAT BALLING business, page 244. As I understand it, E. Franke watched many cases of queens returning from wedding-flights into one-frame fertilizing-hives, where he could see them through the glass sides, and in every case the queen was balled unless she returned without having mated. Did Mr. Pritchard see the queens after they entered, so as to be sure they were not balled? I've seen bees many a time chasing after a queen to pull away the filament, but I don't know that the queen had not been first balled for a time. [Mr. Pritchard has raised anywhere from 1000 to 3000 queens in a season. In the height of the queen-rearing work he is constantly opening baby nuclei. If there were any such balling as Mr. Franke refers to he would have seen it, we would think.—ED.]

## Siftings

By J. E. CRANE, Middlebury, Vt.

Dr. Miller, page 4, refers to the Dadants feeding granulated honey. I will say that I have fed it with very satisfactory results in the spring by placing it on top of frames under a warm cushion.

I can not quite agree with Mr. Byer, page 780, Dec. 15, that honey is unnecessary in a syrup made of two parts of sugar to one of water, for I have seen quite too much that was granulated in the combs when fed without honey.

On page 6 Mr. Wesley Foster's remarks as to the value and advantages of careful grading are well taken. Although there may be local markets that do not require so careful grading, for our larger markets the more careful the grading the better.

Page 4 Dr. Miller says, "If fielders go straight to the supers it seems they might take their pollen there too instead of dumping it in the brood-chamber." Well, my bees often store pollen in the supers, and I believe their methods of storing fresh nectar are very variable.

Decidedly interesting is that account of putting up bees to ship by the pound, with illustrations, pages 50, 51, 52. I do not believe that half the praise has been given the swarming-box it deserves. I believe it should be given a much larger place in our practice than it has heretofore occupied.

If any one thinks that bee-keeping lacks excitement, or is monotonous, let him look at that picture on p. 74, Feb. 1, and read Mr. Holtermann's description of moving bees. I have always moved in cold weather when conditions are more favorable.

Mr. Boardman's method of preventing granulation seems a good-sized step in advance along these lines. He does not say, p. 770, Dec. 15, just how much sunshine is required, nor the temperature, nor how soon after the honey is extracted the treatment must be applied. My experience has not been satisfactory, and I await with a good deal of interest more complete instruction.

Mr. Foster has given us, p. 138, Mar. 1, the best reasons I have seen for using a double-tier shipping-case. The fact that the smaller size will not allow the thin covers to bend down is a decided advantage; also that they will sell for from 10 to 15 cents more per case. Queer; but here in the East the markets have seemed to prefer single-tier cases,

and yet I supposed the Colorado honey was marketed in the East.

Dr. Miller, page 755, Dec. 15, says that we should have an entrance  $\frac{3}{8}$  inch deep and one inch wide for every comb covered by bees for an outdoor entrance. I rather think that depends upon circumstances. Such an entrance would be none too much, surely, with sealed covers; but with absorbent cushions above,  $\frac{3}{8} \times 2$  inches is enough for the strongest colonies.

Absorbing material or cushions are taken up, pages 786, Dec. 15, and 27, Jan. 1. A great deal I find said against the cushions because they absorb the moisture. It certainly seems better to have it in the top packing than on the combs of honey. As soon as warm weather comes they dry out; but one thing should be considered—it takes very little opening on top to let the moisture escape. Boards laid on loosely will answer every purpose.

Mr. Pouders's description, p. 18, Jan. 1, of liquefying granulated honey in hot-water tanks, makes one want to go a good way to shake hands with him. I am sure he could never have written such a description of the vexations of liquefying honey without the experience. I am heartily glad he has something better. We have no gas in this town, and there would seem to be objections to a gasoline-stove; and I would inquire if an oven could not be heated sufficiently with a coil of steam-pipe to melt granulated honey in five-gallon cans.

C. E. Millard, p. 44, Jan. 15, complains bitterly of the ravages of the wax-moth, and I was particularly interested in the editor's footnote in which he says, "Since the Italian bees have replaced the old-fashioned black bees, most of the trouble with moth-worms has disappeared." Would not this be equally applicable to foul brood, at least here in the East? A gentleman from the southwest of our State, at our annual meeting told me that he had had little or no trouble with this disease, as he kept Italian bees, while his neighbors who kept black bees lost considerably, and were greatly injured by it.

On p. 27, Jan. 1, I mentioned the distance bees fly for honey. Recently at our State convention Dr. J. M. Thomas, now president of Middlebury College, told how, more than twenty years ago, he kept bees on the west shore of Lake Champlain, about one-fourth mile from the lake, and lost many bees in crossing the lake, which was, at that point, some two miles wide, the bees crossing to visit the rich white-clover pastures on the Vermont side of the lake. He moved his yard of bees some three-fourths of a mile further from the lake, and his bees were not tempted to cross. In other words, his bees would go  $2\frac{1}{4}$  miles without any intervening pasture, but would not go three miles.

## Bee-keeping in the South-west

By LOUIS SCHOLL, New Braunfels, Texas

### A WARNING TO SHIPPERS OF HONEY; A PLEA FOR BETTER SHIPPING-CASES AND CANS.

Last year the writer called the attention of bee-keepers, especially those of Texas, to the importance of better and stronger shipping-cases or jackets for shipping our honey in cans. Only slight attention, comparatively, was paid to this note of warning; and while a few bee-keepers took up the matter and used better cases, the majority contented themselves with the use of such as are generally put out. Most of these are such frail affairs that they do not carry the heavy cans of honey shipped in them, and reach their destination in the most dilapidated condition. The engraving on page 322 shows only a few such weak cases, taken from a shipment of more than a dozen, all of which were literally torn to pieces, not only exposing the cans to injury, but allowing them to be broken. One leaked very badly, and the results would have been worse had not the honey been mostly granulated, preventing a greater leakage.

While the individual bee-keeper does not have very much loss during a season, which accounts for the slight effort made toward a reformation in better honey-shipping packages, the matter as a whole is a very serious one, as we must consider the many thousands of individuals with the thousands of shipments, many of which are subject to some loss in one way or another. It is impossible to comprehend the extent of these damages to honey shipments without studying the facts in the case. Although I have had an occasional shipment damaged to some extent, in spite of the extra care taken in preparation, it had never occurred to me that more than twice the number of shipments made by us were damaged more or less. This was due to the reason that many consignees do not report back such damages, but put in a claim for recovery at their end of the line. This was at once apparent to me when I saw a list of shipments for which such claims had been put in; for out of the number on the list half a dozen shipments were our own, and of which we had never heard any complaint for damages.

To show the importance of this whole matter I will submit here a copy of a letter received some time ago from an official of *only one* railroad calling my attention to this matter. Heretofore I had not known the seriousness attached to this matter. The letter will explain the situation:

#### HANDLING SHIPMENTS OF HONEY.

*Mr. Scholl.*—I submit herewith a file of correspondence which I am assured is of vital interest to the bee-keepers, or at least to the shippers of honey. The losses of honey in shipment are so great that it not only costs the railroads a great deal of money

each year, but in the end works to the detriment of the man who produces it.

I do not know just how the losses are going to be avoided; but I think that some improvement in the package can be accomplished; and to make this improvement the parties producing the honey must know the weakness of the package used.

I am submitting this correspondence so that you can see the condition of quite a few shipments when they are only half way to their destination. The loss in the rest of the journey can not be expected to be any less. Doubtless a great many shipments are delivered to the consignee with only slight loss, for which no claim is presented, and the retailer stands the loss out of his profits, and naturally the reduction in the profits to the retailer turns him against the commodity on which the profits are unsatisfactory.

I do not know that you can do anything to improve the situation. If you can not, no harm can come from calling your attention to the losses now sustained; but I hope you will be able to accomplish some improvement. After the papers have served your purpose I shall be glad to have you return them to me with such comments as you may have to offer.

Yours truly,

The papers referred to are copies of reports of honey-shipment damages, and claims covering a period of only 27 days, between August 14 and September 10; during which time there were twelve in all. A copy of each of these damaged-honey shipments was appended to the above letter. Each one showed exactly the condition of the shipment upon arrival, extent of the damage, etc. Weak cases, not strong enough to hold as heavy contents as cans of honey; leaks on account of improper soldering; tops worked loose, and contents or part of contents leaked out, etc., were the checks made on these reports.

If we stop to think for just a moment, the short time in which these reports were made, and by only a single railroad, and that after the main shipping season, it must be admitted that the situation is a serious one indeed.

It must also be borne in mind, in connection with the above shipments, that these checks were made when the shipments were only half way to their destination. The shipments reported in the above were from different parts of the State, and from nearly as many shippers, through Fort Worth, Texas, where the checks were made. In what condition these shipments reached the consignees it is hard to say.

Now it is up to the bee-keepers. What are you going to do about it? I have called attention to this before, and it is my hope it will not be in vain this time.

New Braunfels, Texas.

[Mr. Scholl is right. It is strange that a bee-keeper will produce a fine article of honey, and then put it up in a cheap or second-hand package. Cans that have been used once are weakened or rusted. The user of them saves a few cents on the package, and loses dollars where he saves cents. The honey leaks, and trouble occurs between the railroads, the honey-producer, and the purchasers of the honey. No wonder he fails to make a satisfactory settlement with either. Honey, if it is worth any thing, should always be put in *first-class new packages*.—ED.]

## Conversations with Doolittle

At Borodino

### EARLY WORK IN THE SUPERS.

"How can I get my bees to enter the supers early in the season? I know that bees will begin work sooner on empty combs than when they are obliged to build their comb; but I am told that comb foundation will take the place of drawn combs."

"It will when nectar is coming in from the fields fast enough so that the bees begin to secrete some wax of their own; but when the honey-flow begins very gradually, and continues slow, we very often find that colonies provided with combs will make quite a show in the surplus apartment before those with only foundation to draw out, or those which are obliged to build their combs, make any start at all."

"But is it not just as well to leave the supers off during such slow work, allowing this little to be put in the hive for food for the larval bees?"

"No, not by any means. Such a course encourages swarming, which is a detriment in our modern bee-keeping. It is of great importance that the bees begin to put honey in the surplus apartment at the very first of the honey season. They work much better afterward when their first honey goes above, and they are not nearly so likely to fill the brood-combs with honey, and thus curtail the brood through lack of room given the queen in which to lay. Here is one of the great problems in apiculture; for *with the crowding of the queen comes a desire to swarm, which swarming fever is against a good yield of honey, even if the brood was not so curtailed as to injure materially the prosperity of the colony through the whole season, which is generally the case.* By placing a hive of empty combs above each colony as soon as it becomes strong enough to receive them, work will be begun there long before any colony thinks of entering the sections. Then as soon as the bees are well at work in these combs they are taken away from them, and sections put on, in which the bees go to work readily, especially if these first supers of sections contain a few baits. The bee-keepers of nearly a quarter of a century ago found out that, if a hive of drawn brood-combs was placed on a strong colony quite early, the bees would take advantage of them and store honey before they would go into supers with baits. Then after these combs were taken off the bees would at once go into the sections, store first in the baits, then draw out the foundation in the sections next to these, and soon work would be going on throughout every section in the super; swarming would be retarded, and a good yield of section honey assured. The combs in which the bees were at work were put on other colonies not strong enough to occupy

upper stories when this work first began; and when all had been brought up to the occupying of sections except the very weakest, these combs, now pretty well filled with honey, were piled from two to four stories high on these weak colonies, and left for extracted-honey production."

"Was the plan a success?"

"It was very much in advance of the former way of working where sections were only starters or only foundation were put on the colonies, after they got nearly or quite strong enough to swarm; but it lacked some of the better elements of our present-day bee-keeping, the turning of all the honey stored by the bees during any and all years, which was not needed by the bees themselves, into the sections, and that without the necessity of having *any* swarms. A plan for doing this is given in 'A Year's Work in an Out-apiary.' As soon as several of your colonies are strong enough so that a hive containing the full number of worker combs can be put over them without injuring their prosperity at brood-rearing, take off the winter covering from them and first place over the brood-chamber a queen-excluder; on this the hive of combs, and put the cover over the whole. The bees will now go to work in these combs; but instead of taking them off and putting sections in their place, as the earlier bee-keepers did, leave them till the first honey harvest opens, or till white clover is opened enough so the bees have commenced to work on it quite freely. As a rule, no preparations for swarming will have commenced so far, which is better than waiting later. Now set the upper hive down in place of the lower hive and put a super of sections containing baits on top, and on this super place another filled with sections having foundation in them. Next, shake and brush all the bees off their combs and out of the hive, which, up to this time, has been their brood-chamber, right in front of the hive you have just put the sections on, into which they will run as fast as you shake them off their frames of brood. You now have all the bees which were in both hives in what was the upper story a few moments ago; and as the bees have been used to working and carrying their honey into the hive above, so they will continue, going immediately into the sections; and as the queen lays, the honey stored in these combs will go into the sections, together with that coming in from the fields, while the colony finding itself without brood will go to work the same as a newly hived natural swarm, so that all swarming is unthought of, and a large yield of section honey results. Put the queen-excluder you now have out of use over some weak colony, and on this put this hive of beeless brood. And as the season's work progresses put on more and more. I often have hives so used till there are five hives like this all in one pile. And these are the combs which are used to go on top again the next year, the honey which will be stored in them being of advantage the next season."

### General Correspondence

#### THE ESTABLISHMENT AND MAINTENANCE OF A BROOD-CHAMBER.

Eight vs. Twelve Frame Brood-chambers.

BY R. F. HOLTERMANN.

I have used the small and the large brood-chamber, and I should, therefore, be able to speak from an unprejudiced standpoint. This great and important question in bee-keeping in the attitude of bee-keepers toward it reminds me of the "chamber of torture" of ancient times, with the exception that, in the former, there was no way of escape; in the latter, there is left an open way of escape, and they who remain in it do so of their own will.

In my estimation the small-brood-chamber men are in the chamber of torture, the walls of which are gradually but surely closing in. These walls are made up of public opinion, and they are strengthened and reinforced day by day by recruits which come by the way of escape from the chamber itself as it is gradually crushing those who still maintain the ground of adequacy of an eight-frame Langstroth brood-chamber.

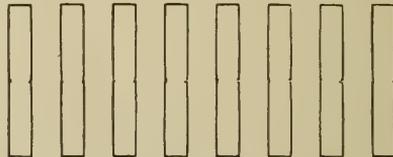

Say what we will as year after year goes by, the question of the size of brood-chamber becomes less and less a question. Apicultural writings, the result of debate at conventions, votes taken at conventions, an examination of the apiaries and methods of progressive bee-keepers, and the trend of orders from supply-dealers, all prove that the sweep with accelerated force is toward the larger hive, and those who advocate them can well in patience await results. If one will look over the writings upon this question in recent times, in my opinion he will find that the large-hive men have appealed to reason, while in some instances the other side has made statements in which ridicule has had a prominent part. For instance, J. E. Hand, GLEANINGS, p. 695, last year's volume, calls the twelve-frame-hive men "honey-slingers." Well, I have always tried to be a man who thought in this world's matters for himself and did not shrink from standing alone at the expense of ridicule. They laugh best who laugh last, and I have already enjoyed many a broad smile in that way.

As I stated at the recent Chicago convention of the National Association, so let me say now, when we study apicultural catalogs and literature, the number of combs in the bottom story makes up the size of the hive, and the number of combs of brood makes the size of the brood-chamber. The English language allows no other interpretation. If the number of combs of brood in the hive really makes the size of the brood-chamber, the difference between a twelve-frame or larger bottom story and the eight-frame bottom story on the tiering-up system can best

be illustrated by the following: In times of intense heat, especially in eastern countries, one man has standing over him a hireling who laboriously, and by might of arm and expense, sways back and forth a fan to cool his heated brow, while his neighbor can turn on, by means of a button, the electric current which regularly, steadily, and at less cost, runs a fan until his good pleasure wills it otherwise. In the manipulation of the small bottom story and the taking of brood to the super we have a far more laborious and expensive process, to say nothing of more radical departures from normal lines. To place brood in an upper story, be it shallow or deep, entails greater expansion and inconvenience to the bees in feeding the larvae and maintaining the heat thereof than that obtained by the adding of combs to the lower story. Then, too, it is more normal, and less of a break to the walk and ways of a queen, to pass from the 8th to 9th and 9th to 10th comb, and so on, than for the queen to leave, as it were, *terra firma* and pass up to the unexplored regions above. The very fact that bee-keepers are found who argue that the queen rarely goes out of the chamber she is in, and therefore queen-excluders need not be used, is an argument that it is more natural for her to move *sidewise* from comb to comb rather than pass from one chamber to another.

No matter what the assertions of all the bee-keepers who ever wrote may be, I know that which I have seen again and again, and that which others have admitted to me, that a queen, when she passes from one chamber to another, does not return as readily to the first as she would pass from one comb to another in one brood-chamber. Her inclination during the honey-flow is to deposit the eggs in that position where the brood will be as close as possible to the honey above; and the result is that she loses valuable time while being forced out of regular paths. Sidewise she readily passes from comb to comb; but up or down she follows the comb; and when she comes to the end of that comb, either up or down, her journey ceases, and she is not so ready to pass a piece of wood, an empty space, and another piece of wood to another comb.

The large-hive men are wise enough not to thwart bees in their natural instincts any more than is necessary to serve our purpose, and therefore we place frames side by side until we have twelve, rather than form a brood-chamber, like

the diagram, or double its capacity at one jump by clapping one shallow chamber on top of another.

To be continued.

[When Mr. Holtermann prepared this article he had not seen the editorial on p. 241 of April 15th issue showing the undoubted tendency of bee-keepers toward the ten-frame rather than eight-frame hive; neither had we seen his article.

While a twelve-frame-hive capacity may be all right, it does not fit standard covers, bottom-boards, comb-honey supers, nor extracting-supers already on the market. Strong arguments can be built up in favor of the same capacity of hive with ten frames, two inches deeper than the regular standard Langstroth, sometimes called the Jumbo. As the Dadants have pointed out, these large frames of Quinby dimensions are splendid for the rearing of brood. In our judgment it is far more important to have a hive that will fit standard supers, covers, and bottom-boards, than one that will fit some standard frame. One can adopt the Jumbo hive and still keep on using the standard Langstroth ten-frame hives and supers. He can use Langstroth frames in Jumbo hive-bodies, but, of course, he could not tier up very well using such frames, nor would it be necessary for him to do so. If a big hive is a honey and a money getter, if it is a non-swarmier, or practically so when operated for extracted honey, then all the arguments that our correspondent has made in favor of the twelve-frame Langstroth will apply with equal force, and more, to the Jumbo, which is, to all intents and purposes, the modern Quinby frame. The Jumbo frame is nothing more nor less than the Quinby having Langstroth length of top-bar and bottom-bar, but Quinby end-bars. In favor of the Jumbo we might say further that the Quinby Jumbo hive, having larger comb capacity per frame, requires less frame-handling. We are not quite prepared to admit that a queen will not go readily up into a second story of a sectional brood-chamber. If a colony is strong enough, if the queen is cramped for laying room in the lower section of a sectional hive, she will have no hesitancy, according to our experience, in going into the next story.

Taking it all in all, one should study his locality very carefully before deciding on a larger brood-nest than a ten-frame standard Langstroth. If extracted honey is the object we fail to see that enough would be gained to offset all the inconvenience of being out of tune with the rest of the bee-keeping world, to say nothing of the added expense of extra-wide supers, covers, and bottoms. If that capacity is better, adopt the Jumbo size of hive that will fit standard Langstroth ten-frame supers, covers, bottoms, honey-boards, hive-stands, winter-cases, and drone-traps.

The Jumbo is a standard hive, obtainable, we believe, from most dealers; while the twelve-frame Langstroth is sold nowhere, and would have to be treated as an odd-sized hive. This would necessitate in the height of the season delay, and an added cost because it is odd-sized. One should consider the matter in all its bearings. See editorial on page 307 this issue.—Ed.]

## DIRECT INTRODUCTION BY THE FAST- ING METHOD.

Laying Queens or Virgins Allowed to Run Directly into the Hive.

BY J. M. BUCHANAN.

As the time approaches for requeening, the bee-keeper looks about for the best method of introduction. It is commonly conceded that the plans in general use are not satisfactory. Dr. Miller asks for a safe method, and is told that there is no absolutely sure plan. As there is nothing about the business of bee-keeping that is absolutely sure, that is perhaps true. During the past winter several new methods, or variations of old methods, have been exploited in the bee-journals, all of which were more or less fussy, and none of which gave promise of much improvement over the plans in general use. For several years I have been using a plan which is at once easy, quick, and sure. As I have tested it thoroughly I can recommend it to the bee-keeping public as something of real merit. Mr. N. O. Walker, President of the Tennessee Beekeepers' Association, and a bee-keeper of forty years' experience, says of it, "This plan is far ahead of any other I have ever used."

Now for actual results: Out of 250 queens introduced by this method during the past three years I have lost only three, and those were given to laying-worker colonies; while during the same time, and under practically the same conditions, I have had about twenty per cent of failures by the ordinary cage-and-candy plan.

Here is the direct method, as practiced in my own apiary: About the middle of the day the old queen is removed; or if the colony has been queenless for more than twelve hours the combs are closely examined, and all queen-cells cut out. This is important. Now get a piece of wire cloth about three inches square. Roll this into the form of a cylinder  $\frac{3}{4}$  inch in diameter. Tie a string around it, and insert a cork in each end. This is our "introducing cage." Just before sundown place the new queen, alone, and without food, in the introducing-cage, and place this out of the reach of any bees, and let it remain thus for three-quarters of an hour. Now the hive-cover is partly removed so as to expose one or two frames, and a very little smoke blown in to drive back the bees. Take out one of the corks of the cage, and let the queen run down between the frames. Blow in another whiff of smoke and close up the hive, and the operation is done.

It seems that the scent of the queen has less to do with her acceptance by the colony than her behavior on being released; if she is frightened, or acts in a haughty or insolent manner, the bees recognize her as a stranger, and promptly sting or worry her to death. If, however, she is lonesome and hungry, as is the case when introduced by this method, instead of running as if fright-

ened, or passing by with an arrogant air, when she meets a bee she humbly begs for food. This is always given, and so all is serene. It is, perhaps, best, though not imperative, for the colony to remain without a queen for half a day, or until they realize their queenless condition. However, I have on several occasions removed the old queen and put in the new one at the same operation, and the bees did not seem to know any difference. Either laying queens or virgins can be successfully introduced by this method.

Not the least advantage of this plan is the small loss of time in egg-laying, as compared with some of the older methods, and this is an important consideration where the queen is introduced before or during the honey-flow.

Franklin, Tenn., April 25.

[This is almost identically the same plan of introducing that is known as the "fasting" method, first fully worked out and placed before the public by Mr. Samuel Simmins in his book, "A Modern Bee Farm," in 1887. It has been continued in all the subsequent editions of the same work. We haven't a doubt that so far as Mr. Buchanan is concerned that the plan was entirely original. While the Simmins plan is not exactly the same, it is so near like it that it may be considered as one and the same. For the purpose of comparison we reproduce the Simmins plan here:

#### SIMMINS' "FASTING METHOD."

long since practiced by myself, and first mentioned in my pamphlet upon Direct Introduction, I have since improved by inserting the queen at night. The three things of importance to be observed are as follows: 1. Keep the queen quite alone for not less than thirty minutes; 2. she is to be without food meanwhile; 3. and to be allowed to run down from the top of the frames after darkness has set in, by lamplight. It is also important that the same receptacle be not used twice over for holding the queen during the thirty minutes' probation without first being scalded or otherwise cleansed. Of course, a metal cage is easily made clean, though there is no objection to the cheap "safety" match-boxes so commonly in use, as there is nothing obnoxious about this kind. My own practice is to carry the queens in the vest pockets, in small tubular cages made of fine perforated zinc or tin, one end permanently closed, while the other end is pressed into a piece of foundation after the queen is in. When ready, remove the foundation and let her run into the hive.

It will be noticed that Mr. Simmins says the queen must be kept alone for *not less* than thirty minutes, while Mr. Buchanan specifies forty-five. And, again, Mr. Simmins directs that the queen be run into the hive after dark, by lamplight, while our correspondent says it should be done just before sundown. We will have more to say about night introduction later. But Mr. Simmins was not the originator of this idea of fasting the queen before introduction. We find references to it in Langstroth's old work, "The Hive and the Honey-bee," and even in earlier writings.

This fasting method of introduction has been discussed in this journal at different times for years back. For example, there is quite a discussion of it on pages 123 to 126 of GLEANINGS for February 1st, 1905. A

further article appears on page 598 of the same volume. But because the plan is old, that does not necessarily signify it is not good. We have used it off and on to a considerable extent. In fact, our Mr. Bain, at the home yard, says he always uses it when taking a laying queen out of a nucleus and introducing her to a full colony in *the same yard*. We will suppose that in one yard bees are working on goldenrod, in another yard bees are doing nothing. To take a queen from the first-mentioned yard and try to introduce her by the fasting method in the other yard might result in her loss. Why? Because the aroma of the goldenrod would possibly make her a *persona non grata* in the yard where there was no such odor. Yes, indeed, the scent factor is very important and can not be overlooked. But he says he would by no means recommend that plan for the average person to follow out, as so much depends on conditions and the time of the year. In connection with this we may possibly lay down some general principles that may prove helpful.

1. When a little honey is coming in, it is much easier to introduce and unite bees than during a dearth.

2. A queen in the height of her egg-laying will be accepted far more readily than one that has been deprived of egg-laying, as in the case of one that has been four or five days in the mails.

3. Some colonies are more nervous than others. To open a hive of such on an unfavorable day might arouse the inmates to a stinging fury. Indeed, such colonies will often ball and sting their own queen when the hive is opened if the day is unfavorable.

4. It is easier to introduce toward night, or after dark, than during the day. The reason of this is that after dark the excitement of the day has subsided. There is no chance for robbing and no reason for vigil. In short, bees are not *expecting* trouble and are not inclined to make any.

5. A fasting queen, or, rather, a queen that is hungry, will usually ask for food, and hence will generally be treated more considerately than one that shows fear or fight.

6. The scent factor can not be ignored. It is because of this variety of conditions, which the average beginner and many old bee-keepers do not understand, that we would not recommend the fasting method, in preference to the caging plan. Mr. Bain uses either, according to circumstances; but with either he says he loses *no queens*. Right here he asked us not to make this statement, because he thought he would not be believed; but we know him well enough to say that he would not misrepresent the facts.

It is possibly true that, when the bee-keeping public becomes a little better educated, it might be safe for queen-breeders to advise the fasting method of introducing rather than the cage-and-candy plan. If they were all like Mr. Buchanan, and other conditions were suitable when the queens were received, we might recommend that plan;

but we doubt if it will ever be safe to substitute it for the cage-candy plan for *queens received through the mails*. Don't forget that such queens are much harder to introduce than those fresh from a nucleus in the same yard. This is the reason, we suspect, why Mr. Buchanan was so successful. If he had attempted that number of queens received from the mails he would have had a much greater percentage of loss.

In the mean time we are glad to get this report from Mr. Buchanan; and in order that we may know how far the fasting method has been successful with others, we solicit reports.—ED.]

### QUEER CLUSTERING-PLACES OF SWARMS.

BY W. A. PRYAL.

Bees, when swarming, are apt to alight in any place; hence we know of the colony of bees that occupied the lion's carcass, as related in the story of Samson, as well as many instances in modern times where they have preëmpted some queer homes. It was only the past spring that I read of a swarm in one of the cities of the State of Washington that alighted on the trolley-pole of an electric car standing at the end of its run. Then, elsewhere, one took possession of a street-car and sent the passengers scampering in every direction. Then we have heard of bees going into caves, rocks, holes in the ground, and into hollow trees, chimneys, etc. The past spring one of my swarms chose to alight as shown in the accompanying half-tone. We have a small patch of red raspberries, some of the canes of which are supported by wires running lengthwise of the rows. The wires are carried by small posts driven at convenient distances, and to these are cross-arms, at the ends of which the wires are attached by staples. It was on one of these wire-supporters that the swarm mentioned alighted. The wire on the left, as well as the berry-vines, had to be removed in order to get a good view of the swarm.

It is a rather novel position for a swarm of bees to assume, hence my sending you it as a curiosity.

Here I might remark,

without trying to be unduly "punnish," if I may be allowed to use such a word, the bees of the swarm shown had not a cross disposition, though they assumed a cross position.

#### HIVING BEES MADE EASY.

One day during the past swarming-season I had several swarms issue the same day in quick succession. The first alighted on the lower branches of a rather young cherry-tree, so that it was an easy matter to secure them with the aid of a short step-ladder. Instead of using a basket into which to shake the swarm I took a pail or bucket made out of a kerosene-can. I had hardly shaken the bees on the cloth upon which I set the hive I intended this new swarm to occupy, when I discovered a second colony sending forth issue. I knew at once where these swarming bees would alight or make for. I lost no time in gathering the cloth about the hive, thus securing the bees in a

NOT CROSS BEES BUT A CROSS OF BEES.

net, as it were. Before I lifted the hive from the ground to remove it to the stand I intended it to occupy henceforth, some of the bees from the second swarm began to eluster on the cloth. I brushed them off and then went about some operations that required my attention. In the course of five minutes I looked over to the aforesaid cherry-tree to see what size of swarm I was getting. Lo and behold, there was no swarm! Closer observation, however, revealed the fact that there seemed to be a goodly number of bees flying about the old oil-can I threw on the ground beneath the tree after I emptied it of the bees I shook from the tree so soon before. Approaching to investigate, I found that the entire swarm had taken possession of the inside of the can, with the exception of a few bees which were hastening to enter. I threw a sack over the top of the can preparatory to getting the camera. When I was ready I partially uncovered the bee-container. Of course, I was not able to show the large swarm that clustered within; but enough bees are shown clinging at the top on the outside to show that something was doing *inside*. It was but a few minutes after the camera's eye winked that I had those bees running into a nice comfortable dovetailed hive. Really, it seemed to have all been done in the twinkling of an eye.

Oakland, Cal.

### THE AUTOMOBILE AS USED BY AN EXTENSIVE BEE-KEEPER.

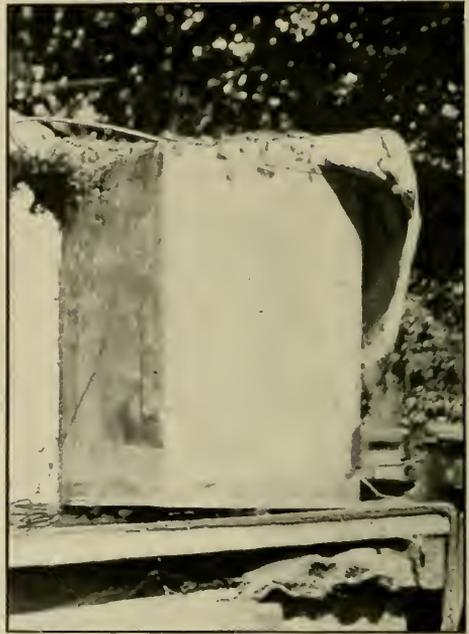

Some Figures Showing Saving in Time and Labor.

BY HENRY STEWART.

[Mr. Henry Stewart is one of the extensive bee-keepers of the country, owning and operating a series of outyards. His experience with the automobile for outyard work will be particularly seasonable and valuable, because the matter of getting to and from outyards without wasting valuable time is of paramount importance.—ED.]

For carrying supplies to and from beeyards I use a Buick automobile, which I find most satisfactory. There are seats for three persons, the small seat behind forming the cover of the tool-box. This I can remove by taking out the hinge screws, and with 2x4 pine pieces I build a platform large enough to take six eight-frame supers without piling them up. This framework just fits in between the fenders over the rear wheels, and it rests on the top of the tool-box. To support the load I extend the two main 2x4's of the frame under the front seat, while at the rear two bolts through the steel frame of the machine hold every thing secure.

To prevent the supers, etc., from shaking off the platform, I have stakes that fit in sockets in the framework. These stand as high as the top over the front seat, and are fastened by straps to the top. When I am carrying a heavy load a rope is placed around the stakes and held by means of hooks to make every thing secure. To

A SWARM THAT CLUSTERED INSIDE AN OLD OIL-CAN.

change the car from a passenger vehicle to one capable of carrying a load, as described, requires about five minutes' work. The load shown in the engraving is made up of sixty 28-section supers. I can travel with the load at the rate of from twelve to twenty miles an hour, and I carry any thing that I could carry in any vehicle of like capacity.

The apiary furthest away is twelve miles from home. To go to this yard with a light load and a team requires two and a half hours with good average driving, with another half-hour for unloading, driving to the barn, putting up the team, etc. Then at noon I have to go back to the barn and feed the team before I can go back to work. At night there is another delay in hitching up. Then if I wish to carry any thing from the yard I must either stay until dark or carry it a safe distance from the bees, and then get it loaded in a hurry before any angry bees have begun to worry the horses. I find that at least six hours of the time is spent going and coming, with the extra work made necessary because of the horses, hitching up, etc.

With the auto I make the run in 45 minutes, and go right up to the bees, turn off the switch, and in five minutes can be at my work. At noon I jump into the car, go about 80 rods to dinner, and when I return I can run right up among the bees again and have no fear of any thing. I put in a full half day's work in the afternoon, crank up the machine, and in 45 minutes am at home getting ready for supper. I save, therefore, four and a half hours' time on a trip.

For my heaviest hauling I use a farm team; but for most of the road work I use the auto, and find the saving of time, when work is pressing, a most valuable feature.

Prophetstown, Ill.

[Mr. Stewart's experience has been quite in line with our own. For the last five years we have used the automobile in going to our bee-yards. It has proven to be reliable; and as a means for getting to the yards quickly it has no equal. Where a man runs a series of outyards a machine will enable him to take care of more bees than he could possibly do in the old-fashioned way with a horse and buggy or a horse and wagon. If his time is worth any thing this is a big item.

As Mr. Stewart says, there is no danger from stings; and the modern automobile, if one has ordinary skill and mechanical sense, will give him no trouble in handling, providing he has a standard make. In this connection it is fair to say that some persons would never be able to run a self-propelled vehicle, because it is not in them to run or drive it. An automobile is something like a fractious horse—it requires a little skill and a little experience to handle it.

We are just beginning to test the motor cycle for outyard work. While it is a splendid one-man machine, it can carry but a very small amount of luggage; and its capacity is, therefore, somewhat limited. But there are conditions under which the motor cycle will do quite as much work as an ordinary automobile at far less initial cost and

far less cost for maintenance. Brand-new machines can now be had for anywhere from \$175 to \$250. We are testing a Harley-Davidson that sells for \$210. As soon as we have had more experience with it we will give our readers the benefit of the information.

In the meantime we are fully convinced that some form of self-propelled vehicle will be almost a necessity for outyard work, especially if there be as many as four or five apiaries, some of the furthest of which are ten or fifteen miles from the home yard. In order to get good locations it is sometimes necessary to go quite a distance. If a yard is fifteen miles away, a horse-drawn vehicle is too slow, wasting too much valuable time. If a man is capable of handling and operating four or five yards successfully, the more actual work among the bees he can do himself, the less he has to hire. If he has to spend half his time on the road he loses practically half of his capacity to make the yards earn him his revenue.—ED.]

#### MEDIUM-PRICED AUTOMOBILES.

##### Steam vs. Gasoline Machines.

BY JOHN P. TULL.

Noticing the few remarks in GLEANINGS about automobiles, will you kindly inform me if you have any knowledge of the Stanley steam car? Have you any in your city? Would you prefer steam or a gasoline car? I may order a car for about \$1000, to seat

HENRY STEWART'S BUICK, MODEL 10, WHICH HE USES FOR OUT-APIARY WORK.

four persons, and am undecided which kind to buy. I feel inclined toward the Stanley steamer, owing to its easy riding, on account of my wife's health. She underwent an operation about a year ago, and is very tender in the side. Any information you can give me in reference to this car will be fully appreciated.

Philadelphia, Pa., April 21.

[There are only two steam automobiles on the market that we would recommend—the White and the Stanley. Both of them are said to be somewhat expensive to maintain. Both use, for the same mileage, from one-third to one-half more gasoline than the regular internal explosion, or what is generally called a gasoline-engine. They are not as satisfactory for winter use; they are much more complicated, have a lot of little dinky pumps, and small pipes that are liable to give trouble. If one can afford a chauffeur, and stand the larger cost for maintenance and repairs, the machine is all right. It is easier to drive than the gasoline-car, is more flexible, is slightly quieter than some gasoline-cars, and can be driven at a slower pace through crowded sections of a city. On the other hand, the gasoline-car has been so far perfected that there are

several machines that can be driven fully as slowly as the steam, and the cost of maintenance is much less than that of the other type.

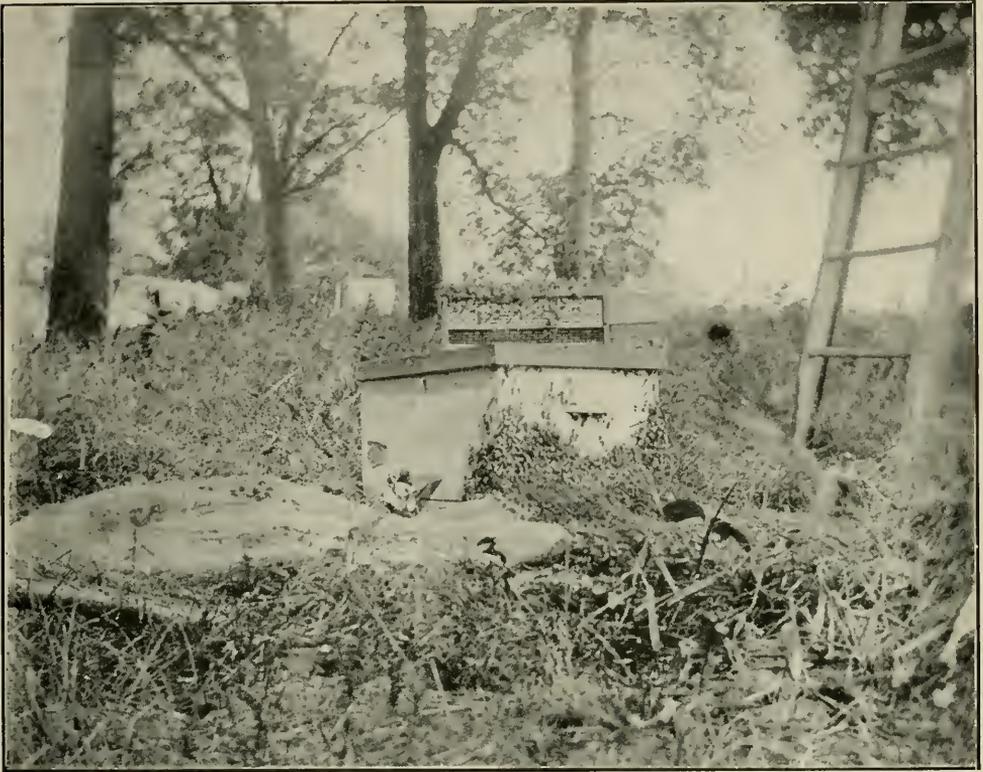

If you want a nice little gasoline-car for about \$1100, that your wife can drive, that is very quiet in operation, quieter than most steam machines, that can be driven at any speed from one mile up to thirty, we would recommend the Cartercar friction drive. It has a very simple transmission, and is about the quietest gasoline-car of which we have knowledge. We have one of them in our family, which runs so quietly that one would think it was an electric. It seats four people, and has a nominal rating of 22 or 25 horse power. The Overland, at \$1000, will carry four passengers. It is a faster machine, and is exceedingly well designed. If you are willing to pay a little more money you will find the Reo \$1250 four-cylinder one of the best machines on the market, built in a large factory, and is first-class in every respect. This will carry five passengers; has ample power, and is backed by a company that has been making good for years. We have driven Reos for the last four years, and have three of them in our family. One double-cylinder car we drove thousands of miles with a maintenance expense of only \$50.00 a year for repairs and tires. Talk with any garage man and he will tell you this is remarkable, and yet the two-cylinder Reo cars have been doing that. You can buy these two-cylinder five-passenger cars for \$1000. They are very simple, and cost of maintenance and repairs would probably be less than any other car you could buy; but it is not as well adapted for city streets, for slow driving, as the Cartercar. The four-cylinder motor makes a more flexible power, and that is the reason why the Cartercar, especially with its form of transmission, would be better suited for your purpose.

The Ford four-cylinder and the Buick four-cylinder are also fine machines. The former can be bought for \$850, and is a five-passenger car. The latter costs about \$1000. If you have a top to either it will add about \$75.00 more to the expense.

We have absolutely no interest in any one of these cars; do not carry any agency, nor do we have any advertising from any of these makes. The writer has made a special study of automobile construction. Owing to the fact that many of our subscribers have been asking for in-

BASKET USED IN SECURING SWARMS CLUSTERED IN THE TOP OF TALL TREES.

THE BEES DUMPED ON A SHEET BEFORE THE HIVE.

formation we have felt it our duty to tell of our experience.

If you were in the country, and wanted to go over very rough or muddy roads we would recommend one of the high-wheeled type of machines made by the International Harvester Company, of Akron, Ohio, or by the Auto Bug Co., Norwalk, Ohio. These are good machines; but they are ungainly-looking. They are not in keeping with the general styles of automobiles with pneumatic tires. For pleasure-driving, the pneumatic-tired low-wheeled machines are much to be preferred.—ED.]

### SECURING SWARMS IN TALL TREES.

BY FRANK C. PELLETT.

Quite frequently the question is asked, "How shall I capture swarms that cluster in tall trees?" The editor always gives the excellent advice to place the apiary where there are no convenient clustering-places beyond easy reach. Perhaps, however, there are others situated as I am, with no such place available, and so I will try to make clear my methods of capturing swarms that have clustered high up above the reach of the longest ladder. Every year there are several such swarms to be considered, and

in some cases they cluster from forty to fifty feet above the ground. After three successive years of tree-climbing, however, let me say that we are preparing to follow the editor's advice to get the bees out of easy reach of tall trees as soon as possible. None of the methods described from time to time have been of any use to me, as my trees are very tall native oaks and elms, walnuts, etc., with few limbs less than twenty feet from the ground.

A painter's extension ladder enables one to reach the limbs, and for the rest of the distance it is simply climb. The accompanying picture shows the basket which we use for bringing the bees to the ground, a large one holding a bushel and a half, with ropes tied across to form a convenient handle. With this basket it is not a difficult matter to get most of the swarms. Simply climb the tree and shake them into it and bring them down. When perchance a swarm clusters so far out on the limbs that we can not use the basket, a sack is substituted. The other picture shows a large swarm that clustered in the extreme top of a large elm. The bees may be seen leaving the sack and entering the hive. This was the most difficult feat of three years' experience, and about cured us of the tree-climbing habit.

ACKERMAN'S APIARY, SHOWING VENTILATING-BLOCKS UNDER THE BROOD-CHAMBER.

Although we have had some bad ones we have never yet failed to get the swarm, no matter how difficult their location, although it is no simple matter to get the sack over a large cluster on the end of a limb forty feet above ground.

Atlantic, Iowa.

[You don't say any thing about clipping your queens' wings. If you practiced clipping all your queens in the first place, there should be little or no climbing of these tall trees. All you would have to do would be to wait for the swarms to return to their respective queens, when the rest would be easy.—Ed.]

### INCREASED BOTTOM VENTILATION TO STOP SWARMING.

The Plan of Raising the Hives from Bottom-boards Practiced Four Years with Good Results.

BY WALTER ACKERMAN.

When the weather gets hot, and bees hang out around the entrances, I put blocks under the hives toward evening, varying the thickness of the blocks according to the strength of the colonies. For instance, if the bees hang out just a little I use  $\frac{1}{2}$ -inch blocks; in other cases I use  $\frac{3}{8}$ -inch; and for colonies that are very strong,  $1\frac{1}{2}$ -inch. By the next day the bees begin to act differently; and so far as preventing swarming is concerned, if this work is done not less than a week before there are signs of swarming, it can be stopped. One needs to be careful,

however, and not let robbing get started. Even though my hives are pretty well shaded I have been providing this extra ventilation for about four years, and I would not think of doing any other way.

In regard to comb-building between the combs and bottom-board, my experience is like that of Mr. J. A. Yeomans, as given on page 638, October 15. I have never had such trouble. The bees use either side of the hive or the ends for entrances.

The illustration shows my yard as it was two years ago. Some of the hives are raised from the bottom-board. The one marked with a cross had four two-inch blocks under it, besides the extra ventilation afforded by reason of the super being moved back. Some of the other hives had  $\frac{7}{8}$ -inch blocks, while still others, being nuclei, were kept closed on account of danger of robbers. I had shade-boards over the hives, but removed them when the picture was taken.

It is very windy here at times, and I need plenty of weight on the covers to keep them from blowing off.

Portsmouth, Ohio.

[Several have already reported favorably on this kind of bottom ventilation to keep down swarming. The trick is so simple, and so easily applied, that we hope many will try it and report. Don't forget that the remedy must be applied *before* the bees make preparations for swarming. In the meantime, there are doubtless others who have tried this ventilation plan for checking swarming. If so, we hope they will report their experience.—Ed.]

### SWARMING.

Some of the Causes that Induce it; Can the Swarming Instinct be Bred out? an Elementary Discussion that will Prove Helpful to Beginners.

BY GEO. W. WILLIAMS.

It is generally understood that swarming, or, rather, the interruption of work, before and after the swarming act, costs a large per cent of the honey we could otherwise secure. It is true that we can, by more or less complex systems of management, partially overcome this loss; but we pay the price in added work, and in worry and uncertainty. What a boon it would be if we could eliminate this troublesome tendency! But can we do it? The logical way would seem to be by selection and judicious breeding, both of which are advocated by some of our best writers. But if we are to succeed we must fully analyze the difficulties that must be overcome.

We must always keep before us the fundamental truth that bees are not reasoning beings to any appreciable extent, but are governed entirely by instinct. We must also remember that, while instinct is knowledge, it is *inherited* knowledge, and it is as unchangeable as the laws of the Medes and the Persians. Hence, under similar conditions the actions and conduct of bees will always be the same, regardless of location. Allow me to emphasize this thought, and put it in the form of an unvarying principle: *Under similar conditions, any given stimulus will at any time produce the same results.*

Another fact we must consider is that bees, being governed entirely by instinct, can have no initiative of their own, but must of necessity be stimulated to any action whatever by outside influences.

Now it follows, that, as bees are governed by instinct, and instinct is stimulated to action by outside influences, if we are to change results from what we have at present, we must change either the instinct of the bee or the surrounding influences. Either one will secure results.

We know that bees will not swarm at all under certain conditions. Given room, a cool and uniform temperature, and freedom from the excitement of other bees swarming, they will not swarm. Inversely, contract and crowd the abode, raise the temperature, and place them among swarming colonies, any bees will swarm. Unfortunately, the conditions that stimulate them to do their best work in storing also stimulates the swarming instinct. This limits the field for improvement in this direction to a choice among the half-dozen systems of more or less successful control by manipulation.

After a trial of any or all of these systems our minds invariably turn toward the other and very desirable thing of changing the instinct of bees so that they will not desire to swarm, no matter how we crowd them nor

how rapid a pace we induce them to maintain.

Upon a careful analysis, this seems less hopeful than the other scheme, unless we could control mating as we control it in our other live stock; for any tendency to improvement in this direction is leveled down by the crushing mass of adverse influences.

When we can successfully control the mating, we can hope for practical results along this line, and not before; for instinct, as I stated before, is simply inherited knowledge handed down from generation to generation from some remote ancestor who somehow acquired it, and it is as real and tangible a portion of the nervous system as the legs or wings are of the body. Hence the young honey bee does not have to *learn* to gather honey nor to build comb, but the knowledge comes to it ready made along with the knowledge of walking or flying. So it seems that, if we are to change the actions of the bees and not change the conditions surrounding them, we must really change their physical structure. We all know what a gigantic undertaking it is to change the length of our bees' tongues, even with millions of tubes of red clover tempting them every day in June, calling on nature to add just one tiny bit to the tips of their tongue so as to sip the precious nectar almost, but not quite, in reach.

How, then, can we hope for any great results in changing a tendency that was implanted ages before Samson found the swarm in his lion's dried carcass, and has ever since been fostered and encouraged by systems of "taking up" the heavy new swarms and keeping the swarm.

If we are to change the physical structure we must do so by subjecting the bees to a sustained condition that does not excite the swarming tendency, long enough so that this portion of the nervous system shall become eliminated by disuse. How long this may be I do not know. I knew two instances where colonies had remained 25 years without swarming, and, when placed in ordinary conditions, they swarmed as freely as if they had never had a vacation. I imagine that, if we were to put a colony into a case isolated from other bees, and leave them a couple of thousand years or so without swarming, and then restore them to ordinary conditions, they would not swarm more than once in two or three years any way; but I should not expect much better results,

There is one thing that offers some slight hope for improvement; and that is, the tendency of some offspring to vary slightly from the parent stock. But in bees and ants the effect of their habits of mating has been to equalize and fix the racial instincts so firmly in their physical structure that sports are rare indeed; but they do occur, and by a combined effort in selecting the non-swarming queens to breed from we may improve in this respect; but it will be a slow process, and in the meantime we comb-honey producers must use the best system we

can find to overcome the tendency. At any rate, these troubles of swarming, foul-brood, etc., are not without their benefits. I can control foul brood, and I can, by a proper system, direct the energies of the bees into the proper channels, and, by my system of shaking, keep their energy keyed up to the proper pitch while the flow lasts; and while I can do these things at a profit, others who possibly could do them, but do not take the trouble to learn how, do not do them, and fail. Otherwise they might be troublesome competitors.

By the way, did it ever occur to you that, if the swarming impulse were eliminated, the building of drone comb would also be eliminated? The thought has occurred to me that, if we could establish and maintain the conditions favorable for building worker comb only (always excepting the time of superseding), the swarming question would be solved.

I have been able to establish, but not to maintain, this condition indefinitely. Now, Dr. Miller, can you not suggest some plan to do so, and thereby place the coping to the splendid monument you have erected to guide the feet of the laity?

Redkey, Ind.

### THE UNDERLYING PRINCIPLE OF SHAKING.

Interchange of the Division of a Sectional Hive  
the More Scientific Treatment.

BY LEO E. GATELY.

Successful honey-producers have reported beneficial results from shaking to increase the energy of bees; and, from the nature of things, others have expressed a strong belief in its efficiency. I wish merely to draw attention to the mistake made in supposing the operation in itself to be in some mysterious way a stimulus, while all such benefits clearly emanate from a change of conditions connected with the manipulation. Let us lay aside tradition and preconceived notions, examining this subject with a desire to know the truth.

The error in concluding that benefit is derived purely through the act of dislodging bees from their combs into a pile before the hive is apparent when the claim is set forth that the disturbance will bring old colonies into some psychological condition which characterizes swarms. If newly hived swarms display an unusual degree of activity, it has been conclusively shown that such energy is not a result of the swarm having issued from the hive, nor its handling in being captured, but entirely from new environments. How frequently is an incidence taken for a cause! and how severely are the poor bees often made to suffer through ignorance and lack of careful investigation! It is the broodless condition of newly hived swarms, and not mental conditions, that is alone attributable to an increased activity.

DAMAGED SHIPPING-CASES.  
*See Bee-keeping in the Southwest.*

Colonies that refuse, during a good flow, to do super work while others may be busy in the sections, will, if investigation be made, generally be found laboring under adverse conditions. They can usually be induced to do so by providing more favorable conditions under which naturally they are inclined to do such work—never through dumping them out upon the grass. Some colonies are naturally inclined to ignore supers because of inferior blood; but more frequently it is the result of extenuating circumstances and surrounding influences.

Shaking will occasionally remove undesirable conditions through breaking into and disarranging the natural order of things; but the benefits are accidental, and he who would be master of the situation must rather locate and remedy evils. Certain it is that the mere act of dumping bees before their entrance, and letting them creep back to their work, is of absolutely no value except when connected with a change of environment. To anticipate beneficial results from indiscriminate shaking would be extremely illogical and inconsistent, as it is simply preventing the colonies from working. On the other hand, intelligent manipulation is imperative and indispensable to profitable honey-production.

By the transposition of brood-sections, users of divisible hives can accomplish in a few minutes, and with a minimum of labor, the object sought by "shakers." To create increased activity positively it is then only

necessary to interchange the two divisions of the brood-chamber, causing the bees to move honey. This scientific operation, practiced at the time of giving surplus receptacles, will compel the bees to begin super work immediately.

In shaking, as in our other operations, let us apply knowledge and scientific principles instead of viewing it in the light of some intangible and mysterious force or freak of nature.

Sebastian Co., Ark.

[We doubt if all of our readers will agree with our correspondent in saying that the extra energy of a new swarm is due to a change of external conditions rather than to any psychological effect. Possibly he is right. In any event, the subject will merit some discussion.—ED.]

### RHEUMATISM AND BEE-STINGS.

An Interesting and Instructive Article.

BY A MICHIGAN COUNTRY DOCTOR.

I have been instructed, amused, and depressed as my mind has been played upon by the various references I have seen in professional, miscellaneous, news, and special journals upon bee-sting poison and rheumatism. I have experienced these different mental modalities as sense, nonsense, and ignorance are exposed by the various writers. I note in GLEANINGS occasional discussions of this subject. I am not an expert in the ways of bees nor in the production of honey. I am only a country doctor who studies, among other subjects of routine, "rheumatism." Any one who is looking for a cure for rheumatism is searching for what he will never find. One who is looking for a relief for *his own* rheumatism may find it.

The old-fashioned notion that there is a cure for a disease—i. e., that a disease, separate and apart from its peculiar manifestations in the person who has it, has a medicine that will operate curatively, is no longer held by any one who has a comprehension of the nature of diseases and the action of remedies. Diseases manifest themselves differently in different people. In one, so-called rheumatism manifests itself in one way; in another person its manifestations are as different as if due to another cause. Some have the pain located in the back, others in the trunk, some in the small joints, others in the large ones. In some the pains are muscular; in others they appear to be in the tendons and sheaths of muscles. In some it hurts all the time; in others pain is periodical, or aggravated by particular conditions. Some have fever with rheumatism, and are sick abed. Some have heart-valves and heart muscle involved. Some can not move; others are so restless they can not keep still. Now, to relieve the particular manifestations of the rheumatic affection a remedy must be selected that corresponds to the individual's case.

Every person has his own individual rheumatism. Be the aggravation in his heart, general muscular system, tendons, sheaths of muscles, joints, or where it may be, it is affecting him differently, and he is a different "rheumatic," just as he may be a child, a grown-up person, one with good habits, is afflicted with other taints, is rugged or weak, plethoric or anemic, exposed or well housed, confined to bed, or impelled to move about for relief, etc.

Physicians no longer prescribe medicines for diseases. They prescribe for the sufferer who has the disease, and dispense the remedy as indicated by the signs and manifestations in his particular case.

The actual cause of rheumatism is not known; but it is known not to be uric acid. Uric acid may be the cause of gout, but not of rheumatism. The opinion generally prevails among scientific physicians that rheumatism is a germ disease, although the exciting microbe or microbes have not been satisfactorily identified (see *Med. Record*, Dec. 11, 1909, p. 976). Some rheumatics are relieved by salicylic acid, some by colchicum, some by aconite, some by one remedy, some by another. There is no specific for it. Consequently, if bee-poison will relieve a form of expression that rheumatism may take, it is foolish to expect it to relieve all, any more than salicylate of soda will relieve all.

There is a type of rheumatism, or rheumatic-like ache and pain, that will be relieved by *apium virum*—the poison of bee-stings. The kind of joint and muscle aches and pains that will react to the bee-poison is that accompanied by local dropsical swellings about the parts affected. The skin around the sore spot is waxy and pale in appearance. The urine is usually scanty. The pulse is quick, hard, and small in severe cases.

Many cases of heart involvement with fluid in the "heart-sack" yield to it. The synovial (or joint) membranes are particularly frequent seats of the swelling that will respond to this treatment.

The cases of rheumatic-like states that will be relieved by the bee-poison are not the most common kind by any means. That is the reason that all who are afflicted with the ailment are not relieved by the treatment. Those cases that have been reported as cured or ameliorated have been the ones to which the poison is remedial; those that have not reacted needed some other kind of remedy, which may or may not have been one of a dozen.

The virus of honey-bees is a commodity in the drug market, and is to be had from pharmacists for dispensing. It has its indications in the therapeutic field, and is in the armamentarium of hundreds of physicians. Those who know how to use it, and who understand its clinical indications, rely upon it with as much confidence as is to be reposed in any drug. I believe that there are dealers in and producers of bee products who can tell something about "orders"

from pharmacists for the "raw" material from which the remedy is produced.

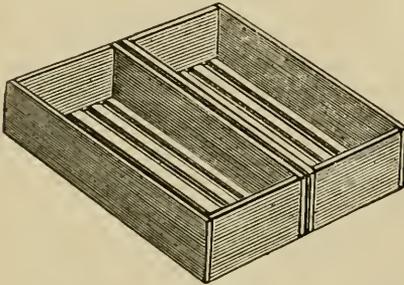

[While our correspondent modestly signs himself "A Country Doctor," one of our staff happens to know something of him. Dr. — is connected with a great institution where his opportunity for observation and treatment of rheumatism is much greater than most doctors have. We know, too, that he had under his care one of the most severe cases of rheumatic affection that is often seen, and this case came from a bee-keeper's family. We can only add that our confidence in his judgment, as shown in the case mentioned, is unbounded, and we know his article is inspired by a desire to be helpful, and to set our readers right on this matter.—ED.]

### PRODUCING COMB HONEY WITHOUT SEPARATORS.

How the Super Should be Arranged; Full Sheets of Foundation in Split Sections.

BY SAMUEL SIMMINS.

Mr. W. Z. Hutchinson and other practical producers claim that they have produced good straight section combs of high quality without using separators, and they are fully justified in making the assertion. Nevertheless, when manufacturers start to offer supers for sections set up without separators they find very little demand for such wares. It may be that the members of our fraternity have not been educated to the use of sections without separators, though I fear many will never take the necessary trouble, slight as

it is, to keep their hives level. That point is, of course, important, more especially where full sheets of foundation are not used and they are not fastened to both sides of the section.

Some thirty years ago I was making strenuous efforts to induce comb-honey producers to make a trial without using separators. I also showed how one might meet the problem half way, as it were, by adopting twin supers with only four sections across (Fig. 17, 1904 edition, "Modern Bee Farm"), or triplets with three sections across. In any of these there are no loose pieces about, and no large number of sections without a separator.

The narrow or vertically divided form of super allows of rapid completion, and permits of further manipulation to that end. It is well known that the end-row sections are often thinner, and frequently delayed in completion; but the twin crates allow of these outer ends being presently turned to the center, and the center to the outside. They are then worked out as perfectly as any. The triplets first illustrated in my 1886 pamphlet allow of similar manipulation, while the central crate is quickly ready for removal.

Perhaps even a greater advantage with these twins and triplets is that of having fixed slatted bottoms. They can thus be placed close on top-bars of the frames below; but note this—always *crosswise* of the frames. Thus the bees have a number of square openings, admitting them to the supers, and those spaces are never filled up with bits of comb, for the simple reason that no place is left for brace-combs between the frames and the first super. Neither is there any space between the additional sets of supers that may be given later—a condition in ordinary supers which sometimes checks the bees, resulting in the upper tiers being badly finished or entirely neglected. Though placed crosswise on the brood-frames, all sets of supers are placed the same way.

You need crush no bees in placing the supers in position, because they are in twins or triplets; and for the same reason the glueing-down causes little inconvenience compared with the manifold advantages derived from the twin or triplet system without separators. A full-size crate with slats close on the frames below would, of course, be somewhat difficult of removal; but the sectional formation on vertical lines is quite a different thing, as a practical worker soon finds.

The slats should not be more than  $\frac{1}{4}$ -inch thick; a  $\frac{3}{8}$ -inch bar is clumsy, and serves to place the sections that much further from the bees below—a detriment, as will be admitted, when first getting the bees to start super work. Many section-frame holders have the bottom-bar  $\frac{3}{8}$  inch thick, and these, again, spaced  $\frac{3}{8}$  inch away from the frames—a most serious impediment, more especially when the apiarist also interposes a queen-excluder.

One reason why the  $\frac{3}{8}$ -inch bar is used under sections is probably because the producer often insists upon working four sections in a frame instead of three, and, unfortunately, the manufacturer appears to encourage this false practice. By spreading sections over too wide a superficial area the combs are not completed so quickly, neither are they finished all around against the wood as perfectly as when fewer are used within the confines of the warmth ascending from the colony. The fact is, a tier of three crates, each holding 21 sections, will be finished off more quickly, and in better condition, than two crates of 24 or 28 sections each.

This point in favor of the smaller number of sections to the crate is intensified when the additional outer margins of space are

given up to packing rather than to a surplus of exposed sections a much smaller number of combs being found in an unfinished state at the close of the season. As an example, a moderately strong stock was supered with a crate of only 16 sections; and within a few days the number was made up to three in one tier. Two were so quickly completed that they were removed and replaced by two others, making five in all (of sixteen each) during a poor honey season, and in little more than three weeks the whole 80 were completed in perfect condition. Colonies in other hives, supered with crates containing 24 sections, and having exposed sides, did not finish off half the number. The small crates of 16 each were within an outer case, and the work was so rapid that the queen had all the stock combs to herself. No excluder was used; and, even if so inclined, she had no chance to start laying where the workers were storing all the honey they brought in. The crates had slatted bottoms resting close on the frame-bars, and each crate close on that below.

If the bees are induced to start off more quickly in the smaller well-protected crate it stands to reason the queen is less likely to be crowded out of her legitimate domain, and the hive has a larger population all the time, while excluders are superfluous.

The twins or triplets with slatted bars may be set on with a sliding motion, starting from the ends of the frames; or any one used to bees can place them after smoking, by a gentle swaying motion that will cause any stray bee to run down.

As illustrated in the 1886 pamphlet issued by me, the outer sections are set against  $\frac{1}{2}$ -inch slips tacked to the sides of the cases, thus equalizing the thickness of the combs. I have never found it necessary to use less than  $1\frac{3}{4}$ -inch sections without separators, and have had no uneven or bad-shaped combs built at that gauge. I have, however, always used full sheets of foundation; i. e., fixed to top and two sides, but  $\frac{1}{4}$  inch clear of the bottom, and I am unable to agree with the editor that foundation showing through the saw-cut is likely to give comb honey a bad name. Full sheets waxed to the top and sides certainly give combs that can be shipped more safely than those combs built from starters only; but the waxing around the sides will surely be objected to as much as the foundation showing through without that rim of wax inside, and which shows up only too well when the comb is cut out. If the waxing is strong, the foundation held in the saw-cut is certainly far stronger for shipping to distant markets.

If it were not for the above question of marketing, and for securing the largest possible quantity of beautiful-looking combs with even worker-finished cappings, one might well agree that there is no comb honey to equal that started from the smallest possible guide of wax, so far as the eating of it is concerned.

A diminished output, however, and a large percentage of broken combs, will not

bring much profit to the producer, nor will the salesman be at all eager to repeat his order for goods that do not arrive in a presentable or marketable condition. Hence while studying the consumer as far as possible the producer can not afford to discard the most expeditious methods of preparing his sections; and I believe there is no quicker way than that of inserting the foundation into sections cut through on three sides—i. e., top and two sides; and, still further, by having the foundation long enough to slip into three or four sections in the same row at one operation—a plan I have adopted for some 18 years; besides sending out large numbers so prepared during that period, without one single intimation that there was any idea of artificial comb honey.

About fourteen years ago I sent GLEANINGS a sample frame of three sections, cut through on three sides, with the full sheet of foundation across the three; but the editor did not seem to catch on to the idea that there was a great saving of time over waxing, and no possibility of any ill-shaped combs caused by foundation falling through the weight and heat of the bees.

I have found little advantage is using high side walls to super foundation, as the bees almost invariably scrape off the raised portions and start anew. I have also reason to believe it is not unusual for them at the same time to alter somewhat the bases of the cells. We hear very little of the VanDeusen flat-bottomed foundation now, but I am of the opinion that *that* kind is least noticeable in the finished product. The very thin base, when altered by the bees, being little if any thicker than the natural comb, is a point that brings us nearer to pleasing the palate of the consumer.

Heathfield, Eng., Dec. 4

## A VISIT TO A CALIFORNIA APIARY.

Prospects for the Season.

BY MRS. H. G. ACKLIN.

The writer took a run a few days ago out to the apiary of D. J. Shultis, secretary of the Los Angeles County Bee-keepers' Club. This apiary, of about 325 colonies, is located a short distance from the Monrovia car line and Santa Anita road. The path to the house leads through an orange-grove, and on the morning of my visit the bees were literally swarming on those full-blooming trees.

On reaching the house a young girl directed me to the apiary, which is a short distance to the north, kindly telling me to call to Mr. Shultis before reaching there, and he would come out; otherwise I might get stung. I walked right in, but did not turn around and walk right out again, as the bees were too busy with orange-blossoms to pay any attention to me.

Mr. and Mrs. Shultis were both as busy as they could be, trying to give the bees room by extracting a few combs from each

super. Two or three hot days had brought the blossoms forward so quickly that they were not prepared for the rush of honey; and the way that orange-blossom nectar was sailing in was a caution.

I was soon ready to pump the smoker for Mr. Shultis while he brushed the bees from the combs. Some of those combs must have contained eight or ten pounds of honey, they were so fat; but I believe some California bee-keepers like fat combs. At any rate, this particular one gave his bees a chance to build them that way, having one or two combs less than the regulation number in each super. The capping on this honey was fully as white as on the white-clover or basswood honey in the East.

The compactness of this apiary was a surprise. There were 325 hives, all facing one way, if I remember rightly, in a comparatively small space—just room enough between the rows, north and south, to run a narrow wheelbarrow. It seems almost any thing can be done with bees when nectar is plentiful; but I wonder if they will be as amiable all this hot summer after the orange bloom is gone.

Mr. Shultis expects to get four tons or more of orange-blossom honey this spring; and as this will be practically the first new honey on the market, it will command a fancy price. The honey-tanks stand out in the sunshine, and are filled by means of a pipe running from the honey-house, several feet distant. They are also near a wagon-road. Room to place a five-gallon can is made in the ground under each faucet, so filling the honey into cans and loading it will be comparatively easy.

In conversing with a gentleman from Canada the other day, who has been in the southern part of the State the past year engaged in the bee business, an interesting subject was touched upon. He claims that wintering is more of a problem here than in his old home. His argument is that the queen lays no eggs during the cool rainy months; but the workers are out, except when it is raining, after forage, which really amounts to but very little, thereby wearing themselves out and reducing the strength of the colony, with no brood coming along to take their places. The consequence is that, when fruit bloom comes on, most colonies are too weak to send out a large force of workers, and so the harvest is lost. On the other hand, bees wintered in a cold climate have been resting for several months, and start out in the spring with a large force of energetic workers. Of course, we all understand that the deciduous fruit bloom comes on much earlier here than in the North and East. How is this, Mr. California Beekeeper?

The late rains have set things a-hummin' in beedom. Bees are being moved to wild-buckwheat fields that would have remained on their winter stands only for the rain. Nevertheless a large honey crop is not expected in Southern California, especially where the sages are the principal forage plants.

Wild mustard grows almost everywhere in great profusion in this locality, and is now in full bloom. Probably it is always in full bloom. I never remember seeing it otherwise. Why do we not hear of wild-mustard honey? If all the waste places were covered with sweet clover instead of mustard, what a jollification the bees would have; and, incidentally, their keepers also!

Mr. C. H. Clayton, of Los Angeles, is experimenting with an uncapping-device which, if it proves a success, will be a great labor and time saver to bee-keepers, and especially so to the apiarist who has hundreds of colonies. I can just imagine the outfit working which I saw standing still the other day. A gasoline-engine was hitched up to our eight-frame extractor, with this device firmly attached to the top of the extractor. The most arduous labor of the beekeeper with that outfit will be to pocket the money from the proceeds of the season's crop.

The next meeting of the Los Angeles County Bee-keepers' Club will occur on Saturday, June 4, in the committee room, third floor, Chamber of Commerce. This club did enough during the first week of its existence to justify its organization. The committee named to confer with the County Supervisors in regard to shipping restrictions got right after its work; and the consequence was that an ordinance was passed prohibiting the shipping of any bees, which were located within twenty-five miles of a district infected with black brood, into this county.

#### Plenty of Honey from the Cow Pea.

Mr. Dillard, April 1, page 235, asks if bees gather honey from field peas. My observation for years has been that the field pea that he refers to, which is the cow pea, not the pea of the North, does produce nectar or some sweet around the joints where blossoms join the upright stems. This is where the bees, and particularly the common red wasps, love to feed. I do not know that the honey-bee can reach the honey in the blossoms. Whatever substance exudes from the point mentioned is not confined to the blooming time alone, but is present, more or less, later, the joints taking on bright or dark red color. My reason for stating that the pea to which Mr. D. has reference is the cow pea is that this is the Southern pea, and should be in bloom late. The Canada field pea, if grown in Georgia, would be ripe and dry by harvest.

Phoenix, Ariz., April 7.

E. T. HUNT.

#### Plaster-of-Paris Method of Killing Rats Very Satisfactory.

I wish to indorse Mr. Hacking's method of exterminating rats, p. 128. I have used it for years, and consider it the most humane, effective, and safe way of ridding the premises of rats. They are hard to catch in traps, and cats as well as fowls are liable to be caught. I would not put out poison for any consideration. I take the precaution to turn a box over the pan of mixture, with the corners blocked up so nothing larger than a rat can go under. This keeps poultry and birds from it.

I do not think it is necessary to put out a dish of water if there is any water to be had within half a mile, for they will immediately go in search of it; and if they have to go a few rods it takes them away so they do not die about the buildings.

If a cat or dog should happen to eat a carcass there would be no bad effect as would be the case if the rat had been poisoned.

from Different Fields

### Disinfecting Hives and Frames ; Honey Vinegar.

1. Is not boiling water sufficient to disinfect foul-brood hives and frames?

2. Can a super of dry combs that has been on a foul-brood hive be used with safety?

3. Last spring I had a few colonies that showed foul brood; but after they swarmed and the new queen had commenced laying it disappeared. When a new swarm is placed on full combs, why would they not work as well in two supers or hive-bodies, with full foundation, as one?

4. How can I make honey vinegar? I put several gallons of honey-sweetened water in a crock last fall, and it is now just as sweet as ever. I have a good deal of very dark honey which is not readily salable, and I should like to make it into vinegar.

5. Is there any way to restore soured honey?

Fenwick, Mich.

C. W. SANDERS.

[1. It is doubtful if boiling water splashed into the hives would be sufficient; but frames should be boiled at least twenty minutes, and we would recommend one or two hours to make sure. We should much prefer to disinfect the hives by means of a flame from a gasoline-torch or burning a little straw inside of the hive, so that every portion of the inside of the hive and the entrance and alighting-board will be blackened but not charred.

2. Yes and no. In the great majority of cases, empty combs from a super above a foul-broody colony will not carry disease; and as there is always danger, we would advise putting such combs in some particular hive and keeping watch of them there. If you wish to be on the safe side, melt the combs up and substitute clean frames with foundation. If the rendering be done properly the price secured from the wax will buy new foundation.

3. A swarm can just as well be placed in two supers or hive-bodies of combs as in one—no advantage in using two unless the colony is very strong.

4. Your honey water was probably too sweet. The late E. France, who used to make considerable quantities of honey vinegar, determined the degree of sweetness by putting in the mixture of honey and water a fresh egg. If the egg would float so as to leave just a spot above the liquid about as large as a ten-cent piece he pronounced it about right. Mr. G. D. Black uses an ordinary hydrometer. This should sink, he says, into the liquid so that the scale will register at 11. It is important to place the sweetened water in a warm place in an open vessel covered with cheese-cloth to keep out insects. The process of making vinegar can be greatly hastened by using "mother" from an old vinegar-barrel.

5. Nothing can be done with sour honey except to convert it into vinegar.—Ed.]

### Making Increase and Changing from Eight-frame to Danzenbaker Hives.

Last year I had one colony of bees, and managed to increase it to four colonies without any trouble, and they are doing finely. They are in eight-frame dovetailed hive. I have now bought twelve Danzenbaker hives with supers and full-sheet foundation. What is the best way to make increase from eight-frame hives to Danzenbaker hives, without swarming? In your booklet, "Facts About Bees," on p. 56, you speak about the queen occupying the cells. How did the queen get there? Was it accidental or was she shaken off into the grass with the bees? On p. 74, Dec. 15, Mr. Barron tells me how to increase on the shake-out plan. Where does he shake the bees? and what does he do with the brood? I wish very much he had told more about it in his communication.

Tilton, N. H., Dec. 25.

F. M. CLARK.

[When we speak about the queen "occupying the cells," p. 56 of "Facts about Bees," we mean *laying* in those cells. You have the impression, somehow, that she went inside of a queen-cell. That is not what we meant. Referring to the item on page 74, Dec. 15, Mr. Barron meant the usual procedure—that is, shaking the bees in front of the entrance.

The brood can be left in the parent hive, for not all of the bees will be shaken out of it. For further particulars on shook swarming see "Facts About Bees," also our A B C of Bee Culture, under the head of "Swarming."—ED.]

### Would Another Swarm Issue Within 30 Days?

When the first swarm comes out, if the old hive with what bees are left, together with all the frames of brood and queen-cells, are moved to a new stand, can two of the frames of brood containing one queen-cell be placed in a hive on top of the old hive, having a queen-excluder between? There would thus be one queen-cell in the top hive, and one in the lower hive with queen-excluder between them. Of course, there would have to be a small opening in the top hive till the young queen has taken her bridal flight. As soon as the young queen has commenced to lay, the top hive could be filled out with frames of foundation. Would such an arrangement cause the lower hive to cast another swarm before thirty days? If one of the young queens failed to return from her flight, the other would most likely land safely.

Colorado.

A. B. CLEMENT.

[There will be no danger of a second swarm if all the cells but one are cut out in the lower hive. As to whether the colony will raise a queen in the second story when they have a perforated zinc, a good deal will depend on circumstances. The bees might and might not allow the virgin in the upper story to remain. A good deal depends on the strain and the time of the year.—ED.]

### The Danger of Sugar Syrup Going into the Supers.

A year ago last fall I fed 26 hives of bees (after I took the supers off) 200 lbs. of sugar, and the following spring I fed those same hives, before I put the supers back on them, 125 lbs. more of sugar, and at the time I put the supers on I had the brood-chambers full of bees and brood and sugar syrup. I believe the bees carried a good portion of that syrup up into the supers. Did I lay myself liable to prosecution for violation of the pure-food law? I sold my honey to the public.

(Gardener, Va., Jan. 29.)

H. HURT.

[It is hardly likely that the bees would carry into the supers the syrup that you fed. The presumption is that it was all capped over before the honey-flow came on. A good portion of it will be used in brood-rearing. We see no reason, therefore, why you could not honestly sell your honey as pure honey. We would, however, avoid feeding just before the honey-flow, for then there would be quite a possibility that some of the uncapped syrup might be carried into the supers.—Ed.]

### Bee-keeping in a Garret Very Simple.

I read, on page 113, Feb. 15, about a colony of bees kept in a garret for eleven years, and that never swarmed. Now, I should like to know if Mr. Stewart ever changes the frames in the brood-nest—that is, took out the old combs and put in new ones, and also if he requeened, and how often, or did he leave it to the bees to supersede her?

Vowinckel, Pa., April 4.

D. P. TOOMEY.

[Mr. Stewart replies as follows:]

In answering the questions submitted I will mention some other things that may be desirable information to some persons desiring to make a start with a colony of bees in a garret.

The hive-stand should be on a level with the bottom of the window, and the window raised about an inch to afford the bees ingress and egress. The glass should be closely covered; and if there are other windows they should be shaded so that the bees see no light except that from the opening at the sill, which is an extension of their alighting-board.

When for any reason the hive is opened for manipulation it is well to open the window, when most of the bees that take wing will fly out. In the colony kept eleven years in a garret without swarming there was no change of frames or combs in the brood-nest, and it was but once requeened by the owner. The bees did the superseding, with the one exception, and in that instance the colony was queenless, and without eggs or larvæ—cause not known. In such a case the colony (without rescue) is doomed. Fortunately this does not often occur.

The main precaution, and practically the only

disturbance of the brood necessary, is twice a year to see that a queen is present (by her works), and that there are sufficient stores—namely, in the spring during fruit-bloom just before putting on supers; and, again, in autumn after the honey season, about Sept. 1, when taking off supers. If either or both are lacking, the only remedy is to re-queen, to feed, or to do both.

Toledo, O., April 7. CHARLES STEWART.  
[We expect to have shortly an article on this subject from another who has had a wide experience with this garret method of keeping bees.—ED.]

### Black Brood and the Sectional Hive.

I wish to thank you for your courteous reply to my criticism, p. 157, March 1, and also to call your attention to another editorial in your issue for June 1, 1909, in which you say, "If black brood should once get started in an apiary of ours we would treat the whole apiary, irrespective of whether individual colonies showed the disease or not." I regard this as sound doctrine, and we would certainly adopt this plan if foul brood of any kind were to break out in our apiary. From this point of view, by employing economic methods of treatment I can not see wherein the sectional hive would be a very bad proposition. Far be it from any desire of mine to cover up any of the weak points of the sectional hive, and it is easy so see that foul brood might get a pretty strong foothold in an apiary where the frames were seldom handled and the brood-chamber divisions interchanged freely.

It is my candid opinion that, if bee-keepers would keep only pure Italians, and see to it that they were liberally supplied with food at all times, there would be little trouble from foul brood or other diseases. The intermittent periods of semi-starvation to which bees are often subjected by careless bee-keepers saps the vital force of the bees and brood, and make them fall an easy prey to disease germs that are everywhere present. An ounce of prevention is worth a pound of cure, and judicious feeding is worth many pounds.

Birmingham, O. J. E. HAND.

### How to Use Unwired Foundation so it Will Not Stretch.

Last spring I inquired as to the feasibility of making increase in an upper story by the Alexander plan of using full sheets of foundation without wiring. I tried it with quite a number of colonies, and it was perfectly successful in every case, the editor to the contrary notwithstanding. The bees occupied the upper story gradually, drawing out the foundation as the queen needed it, making nearly perfect combs—that is, they were perfect except for the space that was not filled above the bottom-bar.

The queen seems to find things exactly to her liking, and just spreads herself over the new combs. The only difficulty is, if the honey-flow comes on early the bees are apt to put a lot of honey in the way of the queen.

The only foundation that was at all stretched was the frame that I sometimes put in the lower story in place of the frame that I take out with the queen on it to put in the upper story. E. L. BROWN.  
Warren, Minn., Dec. 15.

[While one can get fairly good combs drawn out from foundation that is not wired, yet the facts remain that an unwired comb can never be handled as readily and as rapidly, either in or out of the hive, or in an extractor, as one that has been securely stayed; and, what is of considerable importance, even if horizontally wired, foundation will have less elongated or stretched cells near the top-bar.

A great deal has been written on the best weight of foundation to use. The old-fashioned, or medium brood (which, of course, is more expensive by reason of its extra weight), will usually make better combs than the light brood.—ED.]

### A Chicken that Ate Drones but Not Workers; a Remarkable Case.

One day last fall while working in my yard I noticed a chicken at the entrance of a hive, catching and eating bees. I watched him for some minutes. He would catch a bee going in or coming out, or jump up and catch one. I recited a few lines on the demerits of a fowl that would eat a man's bees, and chased him out of the yard. Soon I caught him at

the same performances. I called my wife, and we decided to cut his head off, which we did. Upon examination of the chicken's crop we found it full of drones but not a single worker bee. After the observation I reproached myself severely for killing the goose that had laid for us the golden egg. But the unsolved problem with me is, how did the fowl know the difference between a bee that can sting and one that can not?

Hawthorne, Wis. LEWIS EFAW.

### No Inspector Provided for in Iowa.

I noticed with some amusement the remarks about the Iowa law appointing a bee-inspector. There was such a law passed, but no inspector was appointed. The legislature failed to provide funds to sustain the office, and probably no provision will ever be made. Any advice on the subject will be appreciated.

Anamosa, Ia., April 15. FRANK SNYDER.

[This only emphasizes the great importance of having all foul-brood bills, before they are placed before State legislatures, carefully reviewed by an expert. Dr. E. F. Phillips, of the Bureau of Entomology, Washington, D. C., has made this a special study, and is willing to furnish copies of model bills.

In this case it is possible the Iowa legislature amended the bill, practically spoiling it. This has been done before.—ED.]

### Will Bees Remove Honey-dew from Bait Sections?

In putting bait sections in supers from last year with honey-dew in them, and cutting the caps so the bees will remove it, will the bees put the honey-dew back in the sections again with new honey?

JOSEPH S. BOWMAN.

Harrisonburg, Va., April 16.

[The probabilities are that the bees would not remove the honey-dew from the bait sections unless the brood-nest were running short of stores. Any bait sections containing honey-dew should be consigned to the solar wax-extractor. It would be very risky to put them into a super, expecting the bees to remove it and put good honey in its stead. There is no probability that they would do it. When new honey came in they would store on top of it. Such sections would have to be sold for less price.—ED.]

### Can Old Bees Raise a Queen?

When I find a queenless swarm with a laying worker I give it a comb of hatching brood, and in a few days I put in another comb with eggs and hatching larvæ or a ripe queen-cell. The young bees soon dispose of the laying workers, and they will raise a queen if they have eggs or hatching larvæ. From that I conclude that only bees under a certain age are capable of raising a queen, and that old bees can not raise a queen.

Hully, Colo., Dec. 24.

C. STIMSON.

[The plan you outline for disposing of fertile workers is standard and good; but you are wrong in supposing that only young bees can raise queens. The fact has been proven that old bees, when they have to, will assume the function of nurse bees or of raising a queen.—ED.]

### Honey Secured from the Field Pea only when no Other Source is Available.

On page 235, April 1, a correspondent wishes to know if bees gather honey from common field peas. I have anywhere from five to twenty acres of them every year, and my bees always get a good deal of nice honey from them. I know this to be true, as the peas bloom when there is a honey dearth, generally, and so the bees gather honey from them. However, I notice that they do not work on it much if there is a better honey-plant blooming at the same time.

Raplan, Va., April 4.

G. H. LATHAM, JR.

### Keeping the Bottoms of Hives and Brooders Dry.

Tell A. I. R. that I have discovered that a bunch of straw or hay two inches thick placed under Clough's lampless brooders, either outdoors or indoors, will keep the bottom dry. There will be no warping of the boards. This applies to hives as well in winter when standing low on the ground.

Aurora, Ill., Nov. 19, 1909.

V. W. CLOUGH.

## Our Homes

By A. I. Root

To him that overcometh will I grant to sit with me in my throne, even as I also overcame and am set down with my Father in his throne.—REV. 3:21.

I think I have before used this text about overcoming; in fact, in the fore part of Revelation there are many beautiful texts about this matter of overcoming our fleshly appetites and promptings. God has implanted in us a craving for food, and in his loving kindness he has made most wonderful provision for ministering to our hunger. Again and again I am astonished and surprised at the great profusion of beautiful foods that are just within our reach if we will only put forth our hand and make use of them. In our next issue I have something to say right along in this line about that beautiful new berry of which God has permitted me to get a glimpse and taste; but just now we will consider something else.

God has implanted within us at least two powerful cravings for something that will bless us and do us good if we remember that text about overcoming, but something that will do us terrible harm, and send us down to the bottomless pit if we do not exercise reason and common sense. One extreme would make raving maniacs of the whole human family; "overcoming" makes each one of us, every child of humanity, a temple of the Holy Ghost, a place where that Spirit might dwell and bless us and all humanity. I shall now have to ask permission to touch on something right here that is not often considered very much in print.

Man as well as animals has at least two powerful cravings, or we might say instincts, that God has implanted in us for the preservation, not only of these bodies of ours, but for the perpetuation of the whole human race. I am sure you will excuse me if I go back to chickens once more, for they are my intimate companions, and I see in them God's loving hand from the moment they get out of the shell until they get to full maturity. When a chicken is two or three days old it begins to show its craving for food, and it very soon expresses its thanks to the one who feeds it; and I am sure it shows a sort of affection and gratitude. You can teach this newly hatched chick, or fifty or a hundred of them all together, no end of cute little tricks because of their craving for food. In fact, almost the only way to teach and educate domestic animals is through their love for food. A lump of sugar now and then, or a nice apple, will make a horse remember you, and be glad to serve you in any way in his power. Do not forget to win in this way the confidence and love and good will of every domestic animal you meet day by day. It will pay you in dollars and cents.

Well, your only avenue or gateway to dis-

arm the little chick of his fear, and enable you to teach him so you can call him or pick him up, is through this love for food. After the chick has had enough grain, say chick food, for instance, he will show a wonderful appetite for lettuce or other green stuff after he has smacked his lips over it a little and learned what it is. Then try a little flock, say a week old, with the crumbled yolk of an egg boiled hard, until they have learned what it is. They will have to examine it a little, and swallow some pieces before they understand what it is. But in just a few hours you can get them so crazy for egg that they will be chasing each other frantically all over the yard. Some chopped-up meat or ground bone will answer a good deal the same purpose to satisfy the craving or nature's call for something that will make muscle, bone, and feathers.

Well, now, these chicks show nothing but an appetite for food until they are five or six months old. Then the male portion of the flock will have to be separated from the pullets. They have arrived at the age when nature manifests a most powerful impulse and instinct besides the craving for food. When I got back from Florida, business was crowding to such an extent that my flock of poultry here in Medina had been neglected. They had food enough, but I found *eighteen* full-grown cockerels with about sixty of the other sex. Of course I made haste to put them in the cockerel yard, and clipped their wings so they could not get out, until I could dispose of them in various ways. Their inclosure permitted them to get a glimpse every day of the yard containing the laying stock, and it was interesting to me to study this wonderful instinct I have been speaking about. The eighteen cockerels would not fight or quarrel at all so long as none of the other sex were present.

We will now, if you choose, bid good-by to the fowls, at least for the present. Humanity has appetites in many respects much like those of the chickens. These appetites are gifts from God, and, under proper restraint in the line of "overcoming," they bless humanity and the whole human race; but if permitted to have full sway, without being controlled by reason and common sense, man becomes a raving maniac. Witness delirium tremens on the one hand, and on the other the insane and idiotic asylums, and this nameless crime that prompts men to risk being lynched, or, perhaps, being burned at the stake. When we see how many have been cut to pieces, strung up on a tree, or burned to death by a crazy mob, we wonder how anybody but a crazy man should be tempted to give way to such insane folly; and the crowd that puts them to death without judge or jury is almost as crazy and as much to blame as the poor victim, the colored man, who gives way to his insane passion.

Dear friends, what I have given in the above is only a preface to what seems to be going to prove a great and wonderful reve-

lation from God to the whole human race. May be I am a little extravagant; but you know how much I have said as to the awful waste that is going on here in the United States in the way of spending so much time and money to feed our people. That beautiful prayer says, "Give us this day our daily bread;" but the world is in such haste scrambling after new and good things they seem to have forgotten all about the "bread." Note the multitude of dishes that even yet load down our tables, and as a result employ an army of doctors, surgeons, and specialists of different kinds, besides another and greater army of trained nurses at \$4.00 a day or more, besides the expense of asylums and hospitals for the sick and suffering. I have asked myself, "Is there a remedy, and will there be a turning-point?" Thank God, there *is* a remedy, and the turning-point has come. God has been sending us John the Baptists and other great teachers and forerunners. I told you about Terry's work in our issue for March 15; and I closed the article by what I still consider a wonderful message from Upton Sinclair. Terry, Fletcher, Sinclair, Dr. Kellogg, and hosts of others, are striving to wake the people up and make them understand and *comprehend* why people have aches and pains, sickness and death. With all the advantages your old friend A. I. Root has enjoyed (a near neighbor, comparatively, of T. B. Terry), not until he was *seventy years old* did he discover he could be happier and in far better health without a carefully gotten-up supper, or *any thing* but a few apples after the noonday meal.

Now, I have something more to tell you about this man Upton Sinclair. He is a young man, or comparatively so, and bids fair to be young (if he keeps on) for many years to come. If you have not all read his talk in the March 15th GLEANINGS, I wish you would get right at it and read it, and then after that, hunt up the *Cosmopolitan* magazine for May. If you have not one handy, send and get it. Read Upton Sinclair's article on "starving for health's sake." After you have read it, pass it round to the neighbors. Get as many folks to read it as possible. My first acquaintance with Sinclair was in reading "The Jungle," that book that exposed the *meat* condition of things in our nation—the book that caused President Roosevelt to send for the author and have a conference with him. Now, please do not understand that I thoroughly approve that book, "The Jungle." While I read it and was charmed by the author's wonderful descriptive powers, I was also pained because of some things that I thought should have been left out. Another thing, I could see he was not a professing Christian, and I fear he is not now. Yet he quotes the Bible, and seems to understand what true Christianity is. May the Holy Spirit guide him, and open a way for him to make *still further* discoveries that will benefit the human family. Well, when you read that article

in the *Cosmopolitan* you will discover that Sinclair has gone a little further than I have in dispensing with suppers. When his digestion would not stand the close confinement of writing books and articles for the magazines, he began to skip a whole day, then two days, and then three and four days, and, like Dr. Tanner (who, by the way, was a Medina Co. boy), he found out that people could live a dozen days or more, and not "starve to death" either. By the way, when Sinclair's health began to fail (perhaps through confinement and overwork) he went to Battle Creek, Mich., and there became acquainted with Fletcher and Dr. Kellogg. They three discussed for several days, or perhaps weeks, the food problem and the health problem for a nation of people. At this period in his life Sinclair wrote a book entitled "Good Health, and How We Won It."\* It is a nice large book, well illustrated, and the price is only \$1.20. If some of our experts in poultry, while giving some of their systems, would give us a book like this (almost 300 pages) for the price they charge, it would *look* a good deal better, if nothing more. Well, this man Sinclair has all his life seemed determined to put *bodily health* and *vigor* of both mind and body far above the gratification of *any* appetite. He says in the *Cosmopolitan*, "I have never in my life used tea or coffee, alcohol or tobacco." Oh that our great teachers (and great *doctors*, too), by the way, could stand up before the world and look their pupils full in the face, and say what Sinclair has said! After Sinclair had put on flesh, and got to be almost an athlete, like our neighbor Terry, he felt prompted to give a suffering and sinful world the benefit of his discoveries. He discovered that a man can grow fat by starving himself. You want to get that magazine and look at *pictures* of himself and wife, if you can not take time to read the whole article. I told you that going without my supper of nourishing food gave my digestive apparatus an opportunity to clean out, slick up, and mend things that were breaking down, etc. Well, Sinclair gives the human form divine a still better chance by going without food for several days. Of course he loses flesh; but in an incredibly short time he *gains* flesh again. After a fast of ten or twelve days he commences by drinking milk—a glassful every hour following this with more substantial food later on. He finally gained 32 lbs. in 24 days. After he had tested the matter again and again, and secured such marvelous strength and energy, his wife, who had been for years an invalid, was prompted to try it, although they feared she could not stand the ordeal; but now she too is a smiling picture of health. Look at the picture.

Like T. B. Terry, Sinclair has *nothing to sell*. He has no pay in any shape whatever, save what the magazines and his books bring him. He is beating a path through

\* Frederic A. Stokes, publishers, New York.

the wilderness where all the world can follow if it chooses. He and his wife both say that, after the first day, they experienced but very little inconvenience from hunger; in fact, she walked four miles every morning with her husband for six days in succession.

Now, here something funny comes in. People lost at sea or out on the desert starve to death in a week or less. Perhaps it is because they can not get good pure water. Sinclair drinks freely of pure water, all through his fast, but nothing else. At one time while in California, after having taken a fast of three days, and walking about fifteen miles the last day without any trouble whatever, he came home and read about the Messina earthquake. The papers said when food was brought to those suffering people they tore each other like wild beasts because they were crazed with hunger, for they had been *seventy-two hours* without food. Sinclair also had been without food for the same length of time, and just felt *good and happy*, even after he had walked fifteen miles. How can this be explained? It is very simple. Sinclair's fast was a deliberate and voluntary one; but the Italian people were ignorant, and probably frightened. They did not know any thing about self-control, and had never heard the beautiful text about overcoming. When God created man in his own image he intended man should be Godlike, and have the ability to *rule* and to *overcome*.

Some of you may be inclined to say right here, "Well, old friend A. I. Root, why don't you fast for a couple of weeks and tell us about it? Write up a Home paper, for instance, after you have been two weeks without food, and after you have walked several miles, say toward the last day." Well, dear friends, I have been considering it; but while I am feeling so well, what is the use of my fasting? If I have any more attacks of grip fever or chronic dysentery, I will most assuredly try to follow Sinclair. By the way, he says in that magazine that you had better try it where you can consult daily with some one who has had *experience* in the fast cure. He says the greatest danger is that one gets frightened because friends and relatives declare he is killing himself, etc. Ernest and Huber both protest against my making such an experiment, because of my age; but I feel sure that, if I should undertake such a task with the sole end in view of benefiting humanity, God's Holy Spirit would give me strength, both of mind and body; and God knows that the lesson that is needed just now is one of "overcoming" the promptings of appetite, especially remembering we have it in the words of holy writ, that these bodies of ours are intended to be "temples of the Holy Ghost," and that God did not send us into this world solely to have a "good time" in eating and drinking, and ministering to our lower and baser passions.

May the great Father lead us and guide us; and may he bless Sinclair, Terry, and

Fletcher in their efforts to show us how to attain physical perfection, and how to develop into that *glorious manhood* that the Creator had in mind when he placed us here in this beautiful world of ours.

Ernest declares I must not close this article without quoting a tribute that Sinclair pays to our old friend Dr. Salisbury. Our older readers may remember that our journal has had more or less to say about the Salisbury treatment for the past twenty-five years. Here is what Sinclair has to say in regard to it in the article in the *Cosmopolitan*:

For several months after this experience I lived upon a diet of raw foods exclusively—mainly nuts and fruits. I had been led to regard this as the natural diet for human beings; and I found that so long as I was leading an active life, the results were most satisfactory. But when I came to settle down to a long period of hard and continuous writing I found that I had not sufficient bodily energy to digest these raw foods. I resorted to fasting and milk alternately—and that is well enough for a time, but it proves a nervous strain in the end. Recently a friend called my attention to the late Dr. Salisbury's book, "The Relation of Alimentation to Disease." Dr. Salisbury recommends a diet of broiled beef and hot water as the solution of most of the problems of the human body; and it may be believed that I, who had been a rigid and enthusiastic vegetarian for several years, found this a startling idea. However, I set out to try the Salisbury system. I am sorry to say that it seems to be a good one; sorry, because the vegetarian way of life is so obviously the cleaner and more humane and more convenient. But it seems to me that I am able to do more work and harder work with my mind while eating beef-steaks than under any other régime; and while this continues to be the case, there will be one less vegetarian in the world.

## Poultry Department

By A. I. Root

KEEPING CHICKENS IN FLORIDA, AND SOME OTHER THINGS.

I give the following letter entire because it is a sample of the many kind words that come for my department almost continually. If kind words give inspiration as well as zeal, I certainly ought to have plenty of both.

*Dear Mr. Root:*—I take the liberty of writing to you and calling you "dear friend," as it seems to me as if I had known you nearly all my life through reading your articles in GLEANINGS, of which I have been a subscriber, off and on, for over thirty years. I think your writings have done more for me in the line of trying to live a Christian life than any other one thing—that is, through reading Our Homes. Long live GLEANINGS and the editor of the Homes department.

I wish to ask you a few questions. What is the average price of eggs and of different kinds of grain for feeding, as well as the price of land suitable for raising chickens in your part of Florida? also the price of lumber for building poultry-houses? I am 44 years of age, without a family, and one of the biggest chicken cranks in the country. I have some means, and should like to go to Florida and engage in the chicken business. Your poultry department I read with great interest, and have derived many good points therefrom. I am no stranger to the poultry business, as I have kept as many as 400 at a time.

I have just read T. B. Terry's book on how to keep well, and intend to practice some of his precepts. Binghamton, N. Y., April 26. H. S. THOMPSON.

When I reached my Florida home last November the grocers were paying 40 cents

a dozen for eggs. As they claimed that this price was exactly what they sold them for, we were expected to take our pay in goods; but as they sold all kinds of grain and chicken feed this was easily managed while we had only about 75 laying hens. The prices of the grain in 100-lb. sacks were as follows: Corn, \$1.70; wheat, \$2.30; and a mixture of broken corn, wheat, and other grains, called "corn," was \$2.40 per 100 lbs. We found it rather cheaper to buy the corn and wheat; but as the corn gave a variety which the poultry seemed to enjoy, we fed it more or less with other grain. Oats cost \$1.65, and we used quite a quantity of them for sprouting, especially when we were not able to get lettuce refuse of Bro. Rood. Sprouted oats were furnished by soaking a pailful of oats over night, and raking them into the ground next morning. We endeavored to put in a sufficient quantity, so there were always more or less sprouted oats in all the five different yards. The two acres of land where we keep our chickens cost \$150 per acre; but we are only one mile from the grocery where we bought our supplies. Further away, one could get land at almost any price, say from five to ten dollars per acre and up. A good many make a mistake, however, by not counting the cost of getting to the depot and market through the Florida sand. A great deal of the ground around Bradentown is covered with different kinds of wild grasses, so that it makes a very fair road without very much expense for cleaning off the brush, etc. But where there is a heavy traffic, such as occurs in hauling a big crop of celery to market, the sandy soil soon cuts up so it is sometimes quite a job for a horse to draw even an empty wagon through these sandy places. Notwithstanding the fact of being at a distance from market, I do think that Florida offers wonderful opportunities for the poultry business. Before I forget it, however, I must not fail to mention that eggs went down to 30 cts. not long after the holidays, and then for quite a while they were 25; and when I left Florida the last of April the price was down to 20 cents; but the price seldom goes lower than that.

I have before explained quite fully, I think, that very little outlay is required for buildings of any sort. In fact, the grown-up fowls will roost in the trees, and get along very well without a building of any kind. There are two drawbacks, however, where they are up in the trees: You can not catch them when wanted; and owls and other animals are liable to molest them.

In regard to lumber for building poultry-houses, etc., we get plenty of cull flooring for only \$12.00 per 1000, and our five houses were made almost entirely of this stuff. A very little cheap 2x7 for sills is all that is necessary. The cull flooring and the 2x4 will make such a building as I have pictured and described on page 165.

In conclusion, let me say again that it is beyond my comprehension why more people do not go into poultry, and succeed, down in sunny Florida. Cockerels that

were hatched out in December weighed 2 lbs. each in April, and sold readily for 25 cts. per lb. at the same grocery where I sold my eggs. Fifty cents apiece for chickens four months old is what I call pretty good business. So far as I can learn, there is not a person in Florida offering baby chicks for sale. The pastor of the Methodist Church came down one day, and, after looking over my chicken-ranch, he was so much taken up with it that he at once sent away to *Attica, Ohio*, for 100 baby chicks. He said they offered them for \$8.00 per hundred, safe delivery guaranteed clear to Bradentown. Just think of it! people in a land of almost perpetual sunshine sending up to stormy and wintry Ohio for chicks, and then paying express charges for a distance of toward two thousand miles! It reminds me of the time Eugene Davis told me he had orders for Grand Rapids lettuce, grown in midwinter in Michigan, to be shipped to *New Orleans*, where lettuce can usually be grown in the open air the year round.

Perhaps I should mention one of the objections to the chicken business in Florida; and this is, the stick-tight fleas and other insect pests. Well, although these stick-tight fleas did bother both *us* and the chickens, a year ago last winter, during the winter just past there was hardly a flea visible. Perhaps one reason is that we had plenty of rain all winter, and this is generally death to those insects. Another is that I kept the buildings, and especially the roosting-poles, pretty well saturated with Lee's lice-killer, put on about once a month with a spray-pump. I examined my chickens carefully, both old and young, almost every day, all winter, and I found scarcely a trace of lice or fleas. Besides the spraying we put strong tobacco dust in all the nests. Our 75 laying hens paid the grocery bills for myself and wife, and paid for all the grain for not only the 75 adult fowls, but the entire feed for over 200 chickens.

Of course, I have made no estimate in the above of the time spent with the chickens; but I have kept them just for the fun of it, and not to make money. It gave me healthy outdoor exercise, and paid all the expenses for Mrs. Root and myself; and what more can old people like myself want, any way? Of course, we had plenty of eggs; and (take notice) we had them, even if they were 40 cents a dozen. That made very little difference to us.

BUTTERCUPS UP TO DATE, MAY 6.

My three pullets commenced laying about April 1st, when they were about six months old; and were it not for the fact that one of them persists in laying a good many eggs without a shell, the record of the three would be rather ahead of any of my records with White Leghorns. My brother, who is still in Florida, reports two eggs every day, almost without exception, and quite often three, not counting the shellless ones. I presume this peculiar trouble with the one pullet can be remedied. We are going to do our best at it.

## High-pressure Gardening

By A. I. ROOT

ANOTHER OF MY "HAPPY SURPRISES;" THE NORTHEY BLACKBERRY.

Just once in my life I was called on to take the place of a lecturer belonging to a lecture bureau. My talk was on "happy surprises." I said I had been meeting all my life long with happy surprises, and I expected to find them, even down to old age, or as long as God permits me to live. I said, furthermore, that every follower of the Lord Jesus Christ had a right to expect once in a while a "happy surprise." It was years ago that I gave that talk, and I have thought of it a good deal since. If you wish to enjoy having happy surprises, you must not expect too much. You must not expect too much of poor, infirm, imperfect humanity. You must not expect too much of new localities—Florida, for instance. You must not expect too much when you venture into agriculture, fruit-growing, and raising chickens, for instance. Make up your mind to be satisfied with *small* rewards; and when a big reward does come you will have your happy surprise. You must not expect too much of *yourself*. Do not get the big head. When you get up in the morning and plan what you are going to exploit during the day, do not make your calculations too high. Something is always going to happen that you do not plan for. Remember the words of the dear Master when he said, "Let him that would be greatest among you be your servant." Start out for a lowly place and for lowly things in this world; then when you are called on to "step up higher" you will not only appreciate it, but you will be better fitted to fill the station right.

After this long preamble I wish to tell you something that was indeed a very happy surprise. My neighbor Ten Broek is, like myself, an elderly man, and on account of old age, principally, he is not taking the care of his five acres of land over the fence from my own that he took in former years. At different times he has planted different kinds of tropical fruits on his premises; but as he does not raise stuff to sell, or to only a very limited extent, so long as he has plenty for his own use and to give to his neighbors when they call on him he does not care much about getting great crops. To come right down to it, his place is mostly overgrown with brambles and weeds; and I suppose if he likes to have it that way his neighbors should not object.

Well, I noticed several times along about the middle of April some very large blackberries or dewberries, perhaps you would call them, as it is a trailing bush, scattered in different places over his premises. One day I happened to turn aside from the path not very far from his front door, and I discovered something that made me raise both

hands and say, "Praise God, from whom all blessings flow." I thought at first that it was this same trailing blackberry; but from the few that were just getting ripe I decided it was something else, for they were red instead of being black when fully ripe—a most beautiful glittering deep vermilion red. And that was not all. When I came to test one that was fully ripe and mellow I said it was certainly the most delicious fruit of any sort that ever passed my lips. Now, that is not all. This new plant or berry, for it certainly was new to me, covered a space perhaps as large as a good-sized dining-table. It was rounded up in the center perhaps two feet high—a beautiful oval mound, and this oval mound was, a few days later, a perfect mass of the most gorgeous and beautiful fruit I ever saw on any fruit-bearing plant. Now, that is saying a good deal, friends, for I have seen choice specimens of fruit-bearing trees and bushes pretty nearly over all the United States. When I came away from our Florida home, April 19, the great mound of berries was glittering and sparkling with the gorgeous fruit *all over* that mound; and, as if to set it off with a border, little plants had started out like the rays of a star in all directions; and these little plants were *also* glittering with beautiful fruit. Mr. Ten Broek did not seem to think very much about it, for he was accustomed to such sights. I called the neighbors in, right and left, and made myself at home in his berry-patch until I began to fear he might feel I was trespassing; but my good friend Ten Broek (and he has been my friend for many a long year, for he took GLEANINGS before he ever saw me), when I began to apologize for taking so much liberty, said to me and the friends I had brought along with me, "You need not be troubled, neighbors. My good friend Root has full permission to help himself to *every thing*, and do *any thing* he chooses to on my premises." At this there was a big laugh. But I took advantage of the invitation, and *did* help myself to those wonderful berries. Oh, dear me! if John Lewis Childs should see what I have written above, and go down there and see *that* "wonderberry," what would he not do with it? Well, I started to tell you that, for fear this berry might be poison, like the nightshade, and do harm to humanity, I thought I would give it a good test, and so I ate and *ate* of these ruby blackberries until I certainly would have been injured if they would injure anybody. But they just made me feel good and happy.

When I asked neighbor Ten Broek what kind of cultivation he gave them he said he never gave them *any* cultivation at all. He bought one plant at Reasoner Brothers' nursery, Oneco, Fla., four years ago, and it bore some fruit right away; more the next year, more the year after, and so on until the present season. *He gave it no cultivation whatever*. It just spread out, took root, and managed every thing after its own sweet will. After I learned where he got the plants I told Mr. Reasoner he had better come and

take a look at it. He did not come, but sent me the following:

*Dear Mr. Root:*—Your letter of the 13th is at hand. I am delighted to know that Mr. Ten Broek has made such a success with the Northey berry. The only enemy it has seems to be the thrips. These are driven off by free use of tobacco, which should be used either in powdered form or in liquid extract form just as they begin to bloom. We have a fair stock, and can supply a good many for next winter. The pot-grown plants, of which we have quite a number, may be set *any time*. I shall be pleased to give you some plants. Just say how many you want.  
E. N. REASONER.

Oneco, Fla., April 14.

Of course I got neighbor Rood to go over and look at it. He agreed with me in regard to this wonderful tropical fruit, and I believe he also agreed that it was the most delicious berry he ever tasted.

Now, if I should drop this account right here, would it not be a magnificent advertisement for the Northey blackberry? I found by inquiry that the berry had been known for some years. It very much resembles what our California friends call the Logan berry. I ate quite largely of them some four or five years ago when on the Pacific coast; but, so far as I can recall, this Northey berry has a most exquisite and peculiar flavor that the Logan berry did not have. After the originator of the fruit died, the plant was neglected for some years. Then Mr. Reasoner got hold of it and put it in his catalog, and has sold plants to a considerable extent. My neighbor, Mr. Rood, put out quite a little plantation a year ago or more; but for some reason they did not thrive on his land like the one big plant I have mentioned. Mr. Rood cautioned me a little about making an extravagant write-up. He said, so far as I can remember, something like this:

"Neighbor T. used to have a garden right here where that plant stands, and I think he had gotten the ground up to a pretty good degree of fertility. Another thing, the ground seems to be a little springy on that spot. Right near the plant is an old well, and the water stands within two or three feet of the top of the ground almost the year round. That spot seems to enjoy a sort of natural sub-irrigation."

Just one thing more: Over almost all the State of Florida, the weeds and the commons get burned over almost every year or oftener. Some claim it is better for cow pasturage. Well, Mr. Ten Broek has never permitted his ground to be burned off or pastured off. The luxuriant tropical growth has been coming up and dying down or rotting down every year for fifteen or sixteen years with little or nothing taken away. The consequence is, it has become covered with a lot of humus and vegetable growth, making it in good condition to grow almost any thing. That is why these berries are so much ahead of mine.

You will notice, from Mr. Reasoner's remarks above, that he speaks of thrips; and I think it is those same thrips that hinder Mr. Rood's Northey berry from bearing. There are no thrips nor signs of them on

Mr. Ten Broek's premises. I can not tell why unless it is because of the exceedingly strong thrifty growth.

Mr. Ten Broek has no plants for sale. When I spoke about writing it up he said I should say to you all that he did not want to be bothered with correspondence on the subject. Mr. Reasoner, however, will probably be able to give you plants enough to test it in most localities. I have quite a lot set out near my Florida home, and am going to give it a trial here in Ohio. Perhaps it might save you trouble by saying that Mr. Reasoner's catalog price for potted plants is 25 cts. each.

I have given this Northey berry a write-up because I feel it is going to be a blessing to humanity. One such mound of berries as I have described ought to be worth ten dollars to a family where there are several children. Yes, there is one other difficulty. It is not a "thornless blackberry," as you will soon discover if you get it to grow on your premises. But you know there is scarcely "a rose"—that is, a real nice one—"without a thorn."

---

#### SELLING SECRETS, ETC.

The following, from Prof. A. A. Brigham, of the College of Agriculture of South Dakota, explains itself:

*Mr. A. I. Root:*—Confirming your criticism in GLEANINGS, page 276, concerning a cheap and sure (\$1.00) method of exterminating lice and mites, let me refer you to page 139 of "Progressive Poultry Culture" for the hydrocyanic-acid-gas treatment, and to the previous page for brimstone fumigation. These methods being given, not as "secrets," but as plans in use. The book (of which you have a copy) has been published nearly three years. These methods were published often before that. If needed I can tell of experiences of mine where the hydrocyanic treatment proved *expensive* and *unsatisfactory*, while the old-fashioned "hell-fire" proved *economical* and *effective* in destroying the pestiferous parasites. The former case was that of a brooder-house 40 feet long that had stood empty for over a year, and yet was swarming with mites. I will not burden you with the recital, however, unless you wish it.

I desire to thank you for your earnest exposure of so many frauds and fallacies of the present day.  
Brookings, S. D., April 27. A. A. BRIGHAM.

In view of the above, does it not seem as if the Postoffice Department at Washington should refuse to deliver mail to men or women who deliberately go into this kind of graft—charging a dollar for a simple process that they have copied from some printed book or journal?

In turning to the page mentioned above, I found the process given in detail. Thanks to Prof. Brigham for having called our attention to it. I should like to have him tell us all about banishing the pests from that forty-foot brooder-house.

---

#### KIND WORDS FOR THE HOME DEPARTMENT.

I have been reading a few numbers of GLEANINGS with profit on general subjects; but if you could know the great help which I have received from Our Homes it would cheer your heart and fully repay you for all that you have given in that department. Let the good work continue.  
Cushman, Mass. ASA V. SNOW, M. D.

## Editorial

VERY soon a good many amateurs will have trouble in getting the bees to work in comb-honey supers. Frequently the reason is that there is, or has been, too much room for honey in the brood-combs.

### A GREAT BEE-SUPPLY YEAR.

OUR manufacturing department has been running night and day, and it is just nicely keeping up with orders. Evidently, if the call for supplies means any thing this is going to be a great year for honey. A year ago there was an unprecedentedly heavy demand for bee-keepers' supplies. After the failure of the honey crop of last season it was naturally expected that this would be an off year, and that most of the supply dealers would have a light season. They have been happily disappointed.

### NEW IDEAS.

WE are on the constant lookout for bright, glittering ideas, new kinks of the trade; short cuts; some plan or method to save labor and make the business profitable. We are willing to pay for these ideas, and therefore solicit drawings, models, and photographs; but don't—don't for goodness sake—send us any more schemes for wiring frames or any model or drawing of a new feeder. There is no use in wasting time on them. They are of minor importance, and we can well afford to turn our attention to something that touches more the fundamentals of the business.

### TO WHAT EXTENT HAVE FRUIT INTERESTS BEEN DAMAGED BY REASON OF THE RECENT COLD SPELLS?

A SUBSCRIBER wishes to know to what extent the fruit has been killed throughout the country by reason of the late frosts and freezes. In this locality very little has been hurt; but there are sections in the North and Northwest where the late cold spell has done great damage to the fruit-growing interests, especially the apples. While we certainly regret the damage to the fruit-growing interests, yet what is a loss to the fruit-grower is, in an indirect sense, a gain to the bee-keepers. When fruit is scarce there is more demand for honey, and at better prices.

### THE LATE SPRING CLOVER VERY PROMISING.

REPORTS from all over the country show that the very early spring was delayed by cold or rainy weather. Even at this writing, May 25, the trees in our locality are only just fairly leafed out, and some of the earlier varieties are almost as bare of leaves as they were in the winter. Reports also show that clover has made a wonderful growth. As this is a natural clover year, and conditions have been exceedingly favorable, we are expecting clover honey all through the clover regions.

The deferred warm weather, on the other hand, is going to mean some weak and starved colonies.

### WINTER LOSSES CONFINED TO LIMITED AREAS.

SOME reports have been coming in, showing that there was very little loss of bees in the northern climates during the winter, and no loss in the extreme Southern States; but there was a heavy mortality among bees wintered in single-walled hives just a little north of the Ohio River and in the vicinity of Pittsburg. The very cold winter caught those bees that were not prepared, especially those wintered in single-walled hives. There has been, as a consequence, an unusually heavy demand for bees and queens. Our home yard alone has sold over three times as many bees this year as during the corresponding period of a year ago.

### POISONED BEES.

AS USUAL there have been a few reports from bee-keepers who wondered why their apparently healthy bees suddenly began dying in large numbers. Of course, the trouble does not always turn out to be a case of poisoning from fruit-trees that have been sprayed while in bloom, but it does sometimes. We believe, however, that such cases are becoming rarer. It has taken the fruit-growers a long time to learn that they are doing themselves a double injury when they spray the blossoms—not all of them have learned it yet—and meanwhile the bees, the fruit-growers' best friends, have had to die by the thousands.

### DO BEES WORK MORE READILY ON FOUNDATION THAT IS FRESH?

A FEW years ago there was some discussion on this question, and the reports rather indicated that the fresh foundation was to

be preferred to that which was old. On p. 106 of the Feb. 15th issue, F. Greiner mentions the fact that S. D. House prefers to fill his sections with fresh foundation the very day he wishes to put them on his hives. Since this statement was published, however, we have heard from a number of our readers, and the general agreement seems to be that there is practically no difference between the old and the new foundation as to the way in which it is worked by the bees.

In the April number of the *American Bee Journal*, Dr. Miller was asked what he thought of the matter, and he replied that, although he would put his foundation in sections and have it on the hives within 24 hours after it left the mill, if possible, he thought that, after all, the difference between the new and the old was very little. He cautioned his questioner, however, against putting old foundation on the hives when the bees were idle. This is good advice, and just as good, too, when applied to fresh foundation, as it is a bad plan to put foundation, old or new, over hives during a time when the bees are idle.

Mr. C. P. Dadant, in the May issue of the *American Bee Journal*, in commenting on Dr. Miller's answer as mentioned above, gives a very nice explanation of why there may be some difference of opinion in this respect. He points out that foundation after a time becomes brittle, just as fence wire, even though galvanized, becomes more brittle after a few years. This foundation that is old and brittle can be rejuvenated by being warmed again. Mr. Dadant selected a piece of foundation two years old, and another piece that was fresh, and filled a brood-comb with each kind, putting both combs in the center of a cluster. He found that both sheets were drawn out, and eggs laid in the cells. As soon as the foundation became crowded with bees the animal heat warmed it enough so that it became soft and pliable again, and therefore lost its brittleness. Mr. Dadant points out, further, that if both the old and new are put into *supers* the bees, because of a lack of sufficient warmth at the start, will not hesitate to appropriate the new more promptly because it is more pliable.

#### GIVING CELLS OR JUST-HATCHED VIRGINS TO QUEENLESS COLONIES; TWIN OR SINGLE NUCLEI FOR QUEEN-REARING.

FOR over a year back our Mr. Bain and our Mr. Pritchard, each in charge of different queen-rearing yards, have been pursuing slightly different methods. Mr. Bain, for example, claimed that he could get better queens by introducing just-hatched virgins to his baby nuclei. Mr. Pritchard, on the other hand, claimed that too many of these virgins were killed for him, and he found it very much better to give cells, allowing the young queens to hatch out rather than be let loose.

Both men are good queen-breeders, and

we were at a loss to account for their seeming difference of experience. Mr. Bain right along demonstrated he could introduce these young baby queens to his nucleus hives. He objected to giving cells because the cells, he said, could not locate themselves in the warmest part of the cluster; and, besides, he averred you could not tell from the looks of a cell what kind of a queen was inside. If a scrub or deformed queen hatched, she must be destroyed and another cell given, wasting time. Mr. Pritchard, on the other hand, said that, while he could introduce these virgins, the bees worried them, gnawed their wings, perhaps tore off a leg, and too many of them had to be discarded because of their rough usage.

Yesterday, May 24, Mr. Bain called us out to the yard and said he had found why it was Mr. Pritchard could not succeed in introducing just-hatched virgins to his nuclei. "Why," he said, "it is as plain as day when you come to think about it. Mr. Pritchard uses *twin* nuclei—a bunch of bees and two combs on each side of the division-board—while I pull out the division-board and use the *whole* nucleus box." Then he added, "I have been trying a lot of these twin hives, and I find, like Mr. Pritchard, I can not introduce virgins successfully. Here is the explanation: The side of the nucleus that has a laying queen will draw largely from the other side."\* So saying he showed us a number of "twins" having a laying queen on one side and a cell or virgin on the other. The side with the laying queen in every case had the stronger bunch of bees.

"Now, then," he said, "the influence or odor of the laying queen on the strong side seems to permeate the other side; and when we let loose a virgin they just kill her. But we can give that side a cell; and when that cell delivers its virgin the bees accept her. Again, suppose I take the laying queen out of the strong side and give it a cell. In the meantime the virgin on the other side begins to lay, when almost immediately her side will draw from the other that probably has only a virgin or possibly nothing. You see, the trouble with these twin nuclei is that the side that has the laying queen seems to dominate to a great extent the side that has none. Now when each nucleus is on its own hive-stand, remote from any other bunch of bees, it is possible to introduce these day-old virgins right along. I tell you, Mr. Root, I do not want any more to do with these 'twins.' I want to select my virgins—that is, cull out all but the very best, and give these very best to the mating nuclei."

Mr. Bain went on to explain that we can give two virgins simultaneously, one to each side of a "twin," and all will be well, because one side has no advantage of the other in the queen.

\*The entrances to these twins are on the diagonally opposite corners. It is evident that the odor of the laying queen draws the flying bees over to the entrance where she is laying.

## SOME WAX-RENDERING METHODS OF EXTENSIVE PRODUCERS.

In the April issue of the *Bee-keepers' Review*, Mr. Hutchinson describes the apparatus that Mr. W. J. Manley, of Sandusky, Michigan, uses for rendering wax on a large scale. Nearly all of these appliances are such as can be made at home with the help of the local tinsmith and blacksmith. Aside from a few details of construction the general plan of procedure is just about the same as the one which we have used for about two years, and which we have recommended as being the best plan, all things considered, for the average bee-keeper. Possibly an exceptionally large producer of wax would require more expensive apparatus, but we believe that there are few who produce wax on a larger scale than does Mr. Manley, and it is doubtful, therefore, whether a more expensive outfit would be needed by many bee-keepers.

The comb is melted in a common wash-boiler on a stove, with plenty of water. While this is being pressed, another batch is melting in another boiler. The contents of the first boiler are dipped and poured into a burlap sack inside the press, and all the water is retained so that the refuse is kept in the hot water. After the pressure by means of the screw has been applied for some time, the screw is raised and the hot water again allowed to saturate thoroughly the contents of the sack, on the Herschiser plan. The screw is then turned down again, and the slumgum given another pressing. This can be kept up as long as desired, or until practically all of the wax is pressed out of the cocoons, so that it rises to the top of the water. All the water and wax is then poured into a large separating-tank with a faucet at the bottom, and a gate part way toward the top. Hot water for the next boilerful may be drawn from the faucet at the bottom of the separating-tank; and whenever the layer of wax gets thick enough the pure wax may be drawn off through the gate near the top of the can. The process is thus continued, and a large number of cans, pails, etc., are not needed. In the side of the separating-tank Mr. Manley has a strip of glass so that one can tell where the dividing line is between the wax and the water. When this line is below the upper gate, clear wax can be drawn off. If the dividing line should happen to be just at the gate, a good deal of the sediment that settles into the water beneath the wax would be drawn off into the mold. For this reason the glass in the side of the tank is an advantage; and while we have never used this, we can see that it would be a great improvement. The sediment can be left right in the separating-tank, and lifted out of the water with the thin layer of wax finally left to cool. The hot water may be used over and over again.

While we agree with every step in the system of rendering wax as practiced by Mr. Manley, we believe that, in the matter of the press itself, a change in construction could be adopted that would be both cheap-

er and handier. Mr. Manley has succeeded in building a press depending on the can alone for supporting the bottom, cross-arm, etc.; but the average blacksmith has so little idea of the tremendous pressure exerted by a screw in this way that he generally has to rebuild an affair of this kind about three times before he makes it strong enough so that it will not break. Mr. Manley uses a spider riveted to the side of the can near the bottom. He also uses side hooks for securing the cross-arm to the top of the can, after the construction of the German wax-press. But unless reinforced so heavily as to make the construction pretty expensive, this plan is sure to be too weak for the enormous pressure exerted, and on this account we have always used a plain can made of ordinary heavy tin with a hoop around the top. Our oak cross-arm is supported by a wooden framework and by means of heavy bolts which extend from the cross-arm down through the platform underneath the can. The oak framework is a little cheaper construction, and a much stronger one, and it has the further advantage that it is very easy to attach a couple of hinges to the front of the platform so that the whole press may be tilted up on edge to pour off the wax and water after the last pressing. This avoids the heavy lifting of the hot press, and facilitates the work in every way. When it is desired to lift out the contents of the burlap sack after the wax and water have been poured off, the screw is simply turned up as far as it will go, and the can slid out from under it to a position on the front of the platform, where it is very easily refilled.

In the Feb. 15th issue of *GLEANINGS* for 1908, page 210, Mr. R. F. Holtermann described the Sibbald wax-press, which was very much like the well-known Hatch-Gemmel wax-press, with this exception, that Mr. Sibbald allowed the water to remain in the can so that the refuse would always be submerged. Mr. Sibbald also advised pressing three cheeses at a time by means of slatted division-boards. We are sure that it is a good plan to keep the water in the can during the pressing; but we do not believe it practicable to press more than one cheese at a time in an unheated press—that is, in one which does not stand over a stove or is not heated by means of steam, etc. Apparently, Mr. Manley has also found that it is best to press but one cheese at a time.

A few years ago there were not many bee-keepers who saw the need of a good heavy press for extracting wax from old combs, believing that the solar wax-extractor got practically all of it; or if they did not use the solar they simply boiled up the combs in a kettle, weighted down the refuse with a screen, and dipped the wax off the top of the water—by this process throwing away wax by the hundreds of dollars' worth. It indicates progressiveness when extensive producers like Mr. Manly advocate a method which is both rapid and thorough.

## Stray Straws

By DR. C. C. MILLER, Marengo, Ill.

DOOLITTLE's plan for introducing, p. 247, is entirely safe. I used the same plan, only I merely put the queen and brood in a hive and set it over a strong colony with double wire cloth between the two stories. Less trouble, and safe if weather is warm.

IT IS TRUE, as Mr. Simmins says, p. 324, that  $\frac{1}{8}$  inch greater thickness of a bar makes a greater distance from the brood-comb to sections; but is not the disadvantage over-balanced by the advantage that, the further apart brood-combs and sections are, the whiter the sections will be?

"Do ROSES offer any thing for bees to work on?" is a question discussed with some warmth in *L'Apiculteur*. Some accept and some denounce my statement in a Straw, that bees had torn open buds on my roses. M. Gaston Bonnier, whose opinions are always entitled to respect, says the bees could only have been after pollen.

J. E. CRANE is quite right in saying size of entrance for wintering depends on what's on top, p. 309; and that's true whether outdoors or in the cellar. My bees in the cellar have a 12x2 entrance with sealed top. When I first cellared bees it was just the reverse—every thing sealed tight at the bottom, and all open at top. The whole hive (box hive) was just turned upside down.

ABBE GUYOT has an out-apiary of 9 colonies, 75 miles distant, which he visits only once a year, just to harvest the crop! In his brood-chamber he has 15 frames 13x13—a little larger than a Langstroth frame. Over this a board covering with  $\frac{7}{8}$ -inch holes at the outer edge to allow access to the five shallow extracting-supers. He averages 110 pounds per colony.—*L'Apiculteur*, 135.

GEORGE W. WILLIAMS, p. 321, I don't believe establishing a non-swarming strain of bees is so hopeless as it might seem, even with no control of drones. Please remember that, with full control of queens, by selection you are constantly affecting the drones, making it only a matter of longer time to reach the goal. I believe it's worth your while to try it.

M. E. SEVALLÉ reports, *L'Apiculteur*, 93, that a late swarm was hived in a box, its owner not knowing whence it issued. After eight days, M. Sevallé dumped the swarm on the ground, found and eaged the queen, and the bees soon arose and went to their old home, where they were kindly received. He does not feel sure a swarm would always be kindly received after so long a time; but the plan of finding the mother colony is good.

"DR. MILLER asks for a safe method, and is told that there is no absolutely sure plan,"

p. 313. Oh! but there is, friend Buchanan, a plan of queen introduction that is *absolutely* sure. I have used it for a valuable queen. Take eight or more frames of hatching brood—no unsealed brood—without a single bee; put it in the hive with the queen, over a strong colony, with wire cloth between, and close bee-tight. In five days set the hive on its own stand, giving very small entrance.

KARL GUENTHER, in his 35 years' experience, has seen hundreds of young queens return from their wedding-flight, and thinks that, under normal conditions, they are not balled on their return. That they were balled upon returning to a small hive with glass walls was what might be expected. The light shining in alarmed the queens so as to set them to running, and then the bees balled them.—*Leipz. Bztg.*, 58. Mr. Pritchard is all right. [Mr. Gunther offers a very reasonable explanation of why the queens were balled in those little glass hives; and in this connection it is some satisfaction to feel that our own experience is backed by the thirty-five years of Mr. Gunther.—ED.]

AN EIGHT-FRAME HIVE is not large enough in the breeding season for an extra-good queen. Neither is a ten-frame hive. A second story must be added; and the two-story eight-frame is better than the two-story ten-frame. As the season advances, an eight-frame hive with abundant super room is large enough. But when fall comes the large hive is much better—for the bees. Of course, the lighter hives and lighter supers are much nicer to handle. All in all, I suspect thousands of eight-frame hives are in use where ten-frame would be better. If only one size is to be made, let it be ten-frame, sure. [You say that the two-story eight-frame is better than the two-story ten-frame. Are you sure about that? We agree with you that a ten-frame hive is not large enough for some good queens. There are times when two eight-frames would not accommodate such queens. We have been slowly coming to the conclusion that, even for the production of comb-honey, we should prefer the ten-frame size; and in the case of an extra-prolific queen we would put on an upper story. When she got brood well started in both stories, and it was time for putting on comb-honey supers, we would take off the upper story, crowding the solid frames of brood down into the lower story, and give the other frames to weak colonies. In the meantime we would put on our comb-honey supers, one or two as the strength of the colony might require. With ten frames below filled with brood, the first honey coming in ought to go into the supers. "But," you say, "how about pollen?" Young hatching brood would leave room for the storage of pollen. Or, perhaps better still, we would put on a shallow extracting-super and a comb-honey super. The first mentioned would leave room for storage of pollen. It might be necessary to put a queen-excluder on top of the lower story.—ED.]

## Notes from Canada

By R. F. HOLTERMANN

### PROSPECTS FOR THE SEASON.

Since my last writing, lots of young bees have appeared in the hives; but I am told that even colonies packed on the summer stands, owing to the wet and cold weather for the last two weeks, have not much brood in the hives, and stores are not any too plentiful. However, I believe the bees have made progress while vegetation has advanced slowly indeed. Three white frosts have visited us (May 3, 4, 5), the heaviest on the 4th. The outlook is still good, and a honey crop is now almost a matter of temperature only.

### SPACES OF BEES.

So our good old friend Dr. Miller has joined G. M. Doolittle to the extent of "suspecting" that Doolittle is right when he says, "Six spaces of bees on a frosty morning the first of May is better than more or less." I suppose I am not in it at all, then, when I had to super twelve-frame Langstroth hives on and before April 21. Just the same, I wish Mr. Doolittle lived near me and would make a few exchanges, giving me his colonies with more than six spaces in exchange for six spaces. Can not the difference of opinion upon this subject be laid to management? I doubt very much, where the non-swarming plan is followed out, if bees can be too strong at any time.

### LIST OF APIARY INSPECTORS FOR THE PROVINCE OF ONTARIO IN 1910.

1. J. S. Schrank, Port Elgin, Bruce and Huron.
2. D. Chalmers, Poole, Waterloo and Perth.
3. Wm. Idle, Clarksburg, Wellington and Grey.
4. W. A. Chrysler, Chatham, Lambton, Kent, and Essex.
5. John Newton, Thamesford, Middlesex and Elgin.
6. James Armstrong, Cheapside, Norfolk, Haldimand, and Welland.
7. W. Bayless, Grand View, Oxford and Brant.
8. Alex. Robertson, Waterdown, Wentworth and Lincoln.
9. Arthur Adamson, Erindale, Halton, Peel, and Dufferin.
10. Hy. Johnson, Craighurst, Simcoe and Muskoka.
11. J. L. Byer, Mount Joy, Ontario, York, Victoria, and Durham.
12. W. Scott, Wooler, Peterboro, Northumberland, Hastings, and Prince Edward.
13. J. B. Checkley, Linden Bank, Lennox and Addington, Frontenac and Leeds.
14. A. A. Ferrler, Renfrew, Renfrew, Lanark, and Carleton.
15. Alex. Dickson, Lancaster, Russell, Prescott, and Glengarry.
16. Homer Burke, Tayside, Greenville, Dundas, Stormont.

### IS THERE A "BEST BEE"?

There are so many things that D. M. Macdonald writes that I agree with and consider excellent that I hesitate to comment upon his article on p. 296, May 1, especially as he is a ready lance with his pen.

More than that, owing to some slip I was recently made to say that he was becoming well known as an apicultural writer when I intended to add *on this continent*, as he is already well known in Europe. In defending the black bees against the charge of not defending themselves as well against the moth, he justly points out that, with strong colonies, the wax-moth need never be feared. True; but I have had hundreds and hundreds of instances where, in the same apiary, in strong colonies, the wax-moth larvæ could be found sometimes half a dozen in a black colony. Such instances are rare in Italian colonies. Yes, in this country one can readily find eight or ten larvæ of the moth in a black colony where one would be found in an Italian. This being the case, there must be a point where the black stock succumbs to the moth when the Italian does not. More reason would lead me to believe that the black bee must be less vigilant at the hive entrance when other enemies approach; and experience bears out my reasoning. As to susceptibility to foul brood, I can not prove any difference. In case of what is called American foul brood I doubt if there is any difference; but I find much more dead brood in colonies headed by black queens than with Italian or Carniolan. I say "Carniolan," because we in Canada do not refer to them when we use the term *black bees*. The Carniolan and black bee have characteristics as distinct as the Italian and black; and if any one doubts this statement, let me say, "Your Carniolan bees have little or no Carniolan blood in them."

### \*UNTIMELY BREEDING.

Mr. Macdonald commends black bees for "not breeding untimely." As I understand that term, when comparing Italians and Carniolans with blacks, this is a virtue I have never been able to appreciate in black bees. If bees have been brooding until April 20, they are packed so that brood will not chill, even if the hives are not protected beyond a warm cover and proper entrance. When it rains, and perhaps a few chilly days come, for two weeks, the blacks stop brood-rearing while the Italian and Carniolan bees go on. I like that kind of *untimely brooding*. This untimely brooding of Italians and Carniolans gives me a lot of comfort during the present weather, during a break in a honey-flow—yes, after the last flow and until cold nights come on. The young bees are the heart and soul of a colony at all times. Mr. Macdonald quotes Quinby, "I can often avert a black bee in time to prevent a sting; but he must be a skillful swordsman who would thus parry the lightning thrust of the Italian." Admitting the trait, it just shows the strong, vigile, and active character of the Italian. Something can be said for black bees. They have some traits superior to Italians; but give me the medium yellow-colored Italians in preference to the blacks.

## *Bee-keeping Among The Rockies*

By WESLEY FOSTER, Boulder, Colo.

### THE SECTION-DAMPENER.

The editor says, page 293, May 1, that he would not think the water would pass through more than one row of sections. The fact is, the water runs clear through on to the floor and dampens every groove if warm water is used.

### CONCERNING THE RETAILER.

Mr. Diener, page 249, April 15, takes exception to some of my statements on page 105, Feb. 15. I do not think the retailer is responsible for high prices altogether; but I do think that the retail business is overdone, which makes it necessary for him to make a higher percentage of profit than if a larger business were done. I certainly do not think the retailer is making any more money than he should; but the small amount of business done makes it necessary to charge a higher percentage of profit.

### BEE-KEEPING ON THE "DIVIDE."

We have all thought here in the West that honey in quantities could be had only in the irrigated valleys; but bees get considerable nectar from the wild flowers on the prairie. Some of the "dry" farmers are keeping a few colonies, and are succeeding with them. The bees on the "divide" between Denver and Colorado Springs often make as much honey as do those in the irrigated districts. The divide has a heavier rainfall than most parts of the West, and the wild flowers are very abundant. Many a mountain valley and apparently barren field has surprised the bee-man who showed faith by keeping bees in these districts that are passed over by the general run of bee-keepers. The honey gathered from the Western wild flowers is darker than alfalfa, but it finds ready sale among many people who prefer it to the alfalfa honey.

### AN EARLY SPRING.

Spring came much earlier than usual this year; and unless we have some cool weather to discourage breeding, bees are going to swarm much earlier than usual. The abundance of wild flowers, dandelions, white clover, etc., will be quite a factor in early swarming. If we have abundant showers these flowers will come out in profusion, and the stimulus given the bees will bring swarming within a few days after alfalfa blooms. If our bees get the swarming fever at the opening of the alfalfa bloom we certainly shall have a time controlling it. The outlook now is that we shall have a swarming year. There will be honey, no doubt; but if the bees act the way they have in some previous years we bee-keepers will have a busy time

persuading the bees to live in a sensible number of hives. The wild flowers on the mountains and along the edge of the foothills have been more abundant than ever, so far, and the bees in these places have swarmed already, some few being reported in April.

### LIQUEFYING CANDIED COMB HONEY.

The test given in melting comb honey, page 278, May 1, is valuable to western bee-keepers; but I think it would have come out better if the temperature had been kept between 65 and 75 degrees. This temperature would hardly discolor the honey. However, it would not melt any honey already candied, but would largely prevent further granulation. I melted some candied comb honey, and the color was darkened. The most noticeable feature was the toughness of the comb. It was waxy, and not delicate and crisp, as the comb was before melting. The temperature was between 100 and 105 degrees. Most of the combs sagged a little; a few melted down altogether.

The opinion of all Easterners is that alfalfa honey is worse for candying than any other honey. This may be true; but it is a fact that honey gathered entirely from alfalfa, when weather conditions are favorable for its thorough evaporation, is not liable to candy for over a year. I have seen snow-white alfalfa comb honey heavy in body that did not granulate for two years.

It is not difficult to tell the honey that will granulate from that which will "stand up" for a long time.

Comb honey built during an intermittent flow will candy quite soon. It is light amber or amber in color, and is thinner in body than honey gathered in a continuous flow. Comb honey of a clear white transparency, and heavy in body, may be safely stored away for sale in the spring, as it will remain clear if not subjected to great changes in temperature.

### Bees Gather Honey from Common Field Peas, but they do Not Get it from the Blossoms.

I heard that bees worked only on the stalks of the field peas where the blossoms drop off, so three years ago I made some observations; and in every case I found that not a bee worked on the blossom. They were working at the point where it dropped off, pod and all. A sweet substance is secreted here, and the bees worked on this. I wondered if there was any nectar inside the blossoms; so I pulled quite a number apart, and in every instance I found that the little pod was just bathed in nectar, although the bees did not notice it nor seem to know how to get at it.

Last summer I had near the house a small patch of peas that was covered with bees from morning till night, so I made some more observations. Nearly all of them were working on the stalks as usual; but here and there I saw a few Italians pushing their tongues down into the blossoms, as the blossoms are not closed the entire length on the upper side. I intended to go back with some flour and mark the bees that were working on the blossoms, and note the hive that they came from, in order to raise some queens from this strain, but neglected to do so. I believe if we could raise bees that would work on the blossoms it would make quite a difference in the yield of honey here. I have never noticed any pollen from the field peas.

Fremont, Mo.

## *Conversations with Doolittle*

At Borodino

### EMPTY COMBS AS FEEDERS.

"It is only an occasional season that it seems to pay me to feed: I live where bass-wood is about the only surplus I can count on; and after apple-bloom there is little the bees can get between; and when they fail to secure enough to keep brood-rearing prosperous through June I believe it pays to feed. I did not want to go to the expense of buying feeders, so I thought I would fill a lot of empty combs I have with syrup; but on trying to do so I failed to get much into the cells. Can you tell me how it is done?"

"If you lay an empty comb flat and pour liquid on it, instead of the liquid running into the cells, as you would think it would do, it simply stays on the surface or runs off at the sides, very little entering any of the cells. But should you hold the liquid three or four feet above the comb you will succeed better than by pouring it on in the most natural way, with the vessel containing it near the comb. But even at the height of four feet, if a portion of the syrup falls in a compact mass it will not enter the cells, as it can do this only by forcing the air out. Where the syrup presses with equal force over all parts of the mouth of any one cell there is no chance for the air to get out, and the cell remains empty. The drop or stream of syrup must be smaller than the inside of the cell in order to enter it readily, therefore the smaller the drops we can have, the better our success. To this end, if we take, instead of a dipper, the watering-pot we use in the garden during a drouth, fill it with syrup, and hold it up from the combs three or four feet we shall be able to fill most of the cells as we desire. Syrup as thick as we often want to use for feeding will not readily pass through the rose of a watering-pot unless hot; and if hot enough so it becomes thin it will melt the combs so as to destroy our feeders. But we can use "one-to-two" syrup as warm as 110 degrees without danger to the combs, and this will be just the right heat to be comfortable to work with.

If you do not have more than ten or fifteen combs to fill, lay one of these flat down in the bottom of a large dish-pan or wash-boiler. Hold the watering-pot, filled with 110-degree syrup, a few feet above the comb, trembling the rose a little as you pour, so that not all strikes in the same place. As soon as one side is filled, turn the comb over and fill the other side in the same way. In this way keep on till your combs are all filled. If syrup accumulates in the bottom of the boiler, pour it back into the watering-pot, being careful that you do not spill any outside the dishes you are using, and thus make a muss sufficient to make you wish you had procured feeders different from frames of comb."

"But these combs, when filled, make feeding easy by setting them in colonies lacking stores, do they not?"

"Yes. I have thousands of such, and consider this the very best way to feed unless I can have frames of sealed honey to set in, instead of these frames filled with syrup."

"But how about the drip?"

"By setting empty hives over a wash-tub, and hanging the frames in these as fast as filled, the tub will catch all drip so it can be saved."

"But I wish to use several hundred of these combs of syrup. I judge the watering-pot is too slow for so many."

"Years ago I used a tin pan the size of one of my frames, and four inches deep. In the bottom of this I punched holes (from the inside) about the size of those in a rose used for garden-watering. These were in rows  $\frac{3}{4}$  inch apart, and the holes  $\frac{1}{2}$  inch apart in the rows. This dish was set on two strips which were fastened to the top of a bench four feet high, the strips jutting out from the bench so that the dish rested on them at each side, and came out over the floor below, sufficiently so that a large wash-tub could be set underneath. On the bench, a honey-extractor can was installed, so that the gate was over this pan, punched full of holes as I have described. This can, minus the extractor-reel, was filled with syrup of proper temperature, a wire-cloth herb-strainer being fastened to the faucet, so that the holes in the pan would not be clogged by any foreign substance which might get into the syrup. Some sheets of tin were fastened on a trough made of boards set on a little incline, the lower end of which came so that all drip would run into the washtub, and over this trough were set hives to take the frames of comb as fast as filled. With the needed assistant, all was ready. I sat on a stool by the wash-tub, with rolled-up sleeves so I could hold the frames of comb near the bottom of the tub. The assistant opened the faucet just enough so that the syrup would run from each hole in the dish, when, by moving the frame about a little from side to side, the cells were all filled instanter, the frame turned over, and the other side filled as quickly. The assistant then handed me another empty comb, taking the filled one and hanging it in one of the hives standing on the trough, carrying it along over the trough and hives so no drip would get on the floor. In this way I would have the frames filled as fast as he could hand them to me, and put the filled ones in the hives, often filling over 100 an hour. The drip, and whatever fell into the tub, was emptied into the extractor-can as often as necessary, the strainer catching all particles of comb or dirt that accumulated, so that with this and the necessary feed the can was kept full as long as we had empty combs; the cost of all feeders saved, and the feed put right in the hive among the bees just where I wished it, with no danger of robbing in times of the greatest nectar famine by setting in these filled combs in the twilight."

## General Correspondence

### EXTRACTING DURING THE HONEY-FLOWS.

#### Stacking up Supers vs. Extracting Frequently During the Flow.

BY G. C. GREINER.

[Fortunately the number of bee-keepers who extract honey before it is at all capped is growing smaller—many of the prominent producers even going so far at present as to do no extracting until the end of the season, stacking up the supers four and five high. The writer of this article represents the majority, probably, who, during the flow, extract all combs that are nearly capped over.—Ed.]

The question which I am frequently asked, "Would you advise me to produce comb or extracted honey?" must be decided by every bee-keeper according to his natural inclination and surrounding conditions. The main point that should decide the matter is our outlet or demand. If we have a ready market, and are fortunate enough to live in a locality that produces a fair grade of honey, the production of extracted honey is certainly advisable.

But, above all things, nothing but a prime article should ever be taken or sent to the market. The importance of this point is nicely brought out by Mr. Townsend in his "Two-can article," published in the *American Bee Journal* a short time ago. I fully agree with Mr. T. that a poor article will ruin our trade; but I have to differ with him on the management of producing a prime grade. My methods are so different from Mr. T.'s, with some important advantages thrown in, that a brief description of my *modus operandi* may be a help to others who are situated as I am. But before making the attempt I will make a few general remarks, lest Mr. T. and his adherents may get scared.

For years I have practiced extracting during the honey season, commencing when my combs are capped three-quarters or over. Of course, I do not suppose that all my combs are in just that stage of progress. I may find some that are all capped, and occasionally one not quite three-quarters; but if such a one comes in rotation with the lot to be extracted, it goes into the extractor just the same.

I sell at least nine-tenths of all my crop direct to the consumer, which brings me in close contact with that class of people who actually use and test my honey; and if it did not give entire satisfaction, I would be very apt to hear about it. But, instead, I have, during the last eight or ten years, built up a honey trade, with a reputation for extra-fine honey, that any honey-producer might be proud of. In a sense, I am a professional honey-producer—that is, I depend on the product of my bees almost exclusively for my daily bread and butter, and

I expect to do so just as long as Providence permits. This being the case it would be very poor policy to produce an article that would spoil my own market.

Several reasons induce and compel me to extract early. First, if I should leave my honey on the hive until after the honey season, as Mr. T. advises us to do, it would be next to impossible to extract it. It would become so thick and heavy that a good portion of it would adhere to the comb and be lost as surplus. When I extracted last summer, early as it was, with now and then little patches of open honey, I had to do quite a little cranking to throw it out of the combs, and after it was out it was very slow to run out of the two-inch honey-gate of the extractor.

Second, my customers are always anxious to get some of my first honey. Whenever I am in the city during spring or early summer, my customers frequently hail me on the street: "When will you get some of your honey to the market?" or, "Haven't you any honey to sell yet?" or, "Bring me some of your first honey you have to sell," etc. These are expressions I hear time and again. If I should wait until fall before I extracted, my customers would lose their patience and supply themselves from some other source, and I would lose my trade. As it is, a large share of my crop is sold, and the money in my pocket, before Mr. T. even thinks of extracting.

Third, I believe the use of one extracting-super, instead of tiering up, increases my honey crop. The constant changing and shifting of combs, which is necessary with my management, seems to have an energy-producing effect on my bees. The shaking-energy-into-bees theory, which some of our friends advocate, seems to find here practical application. On the other hand, if the forces of a colony are scattered through three or four sets of extracting-combs, empty or filled, idly taking care of uselessly spread-out premises, how can they be gathering and ripening honey? They can not do as effective work as when all forces are concentrated in one super close to the brood-nest.

It may be well enough to say a few words about my appliances, and why I use them. As I am a strong advocate of perfect uniformity in every thing where possible, I use the Jumbo frame, both in brood-chamber and extracting-super. I am thereby enabled to change frames back and forth. It is sometimes very desirable to move combs of brood from the brood-chamber to the super, and at other times combs of honey in the opposite way. It is the same with the super and the brood-chamber. At a minute's notice one can be used for the other. By simply hooking or unhooking the bottom, as the case may be, one is the other whenever desirable.

Then I use to each hive one extracting-super only. I am partly compelled to do so. My physical condition, as a consequence of advanced age, prevents me from

practicing the tiering-up plan. One of my supers, when ready to raise, weighs between 75 and 80 lbs., which is more than I care to handle right along. I am, therefore, compelled to remove my crop by the single comb.

Another item that should be taken into consideration is the additional expense of getting stocked up. It would require quite an amount to furnish the necessary outfit for the season's crop if left on the hives until fall, besides the handling and taking care of so much more paraphernalia.

In brief, I manage my extracting in the following way: As soon as the season is far enough advanced to show signs of incoming honey, all better swarms are supplied with their supers. This generally takes place during fruit bloom, about the 20th or 25th of May. When the white-clover flow begins, or a little before, all the rest that promise fairly well are also supplied to make sure that all have room for storage. As the flow advances, and the strong and best-working colonies are filling up, I take from two to four of their heaviest combs and exchange for empty ones from the weaker colonies that have not started yet. The bees that adhere to these full combs, I try to shake in front of their hives; but I am not very particular if a few bees are left on the combs.

Two or three days after the first exchange was made, the inserted combs in those strong colonies are probably full again, and need exchanging a second time. When this is done, all the bees are left on the combs taken from colonies that are overly strong, and exchanged for empty ones of the weakest swarms. In this way I hit two birds with one stone—I control swarming with one lot and build up another to proper working condition.

About this time I have no more empty combs in weak colonies to draw from, nor storage for full ones over weak colonies. All need their empty combs for their own use, and the extractor has to be called into requisition to help out. The combs that were not exchanged, but were left in the strong colonies from the opening of the season, are now more or less capped, and have to be extracted to provide storage where needed.

With a comb-basket full of empty combs I go to the first hive that needs more room and exchange all the combs of honey, fit to be extracted, for empty ones. The full ones are taken to the honey-house, and extracted, after which they are taken to the next hive that needs more room, and exchanged as before. In that way all crowded supers are relieved of their overplus.

When the comb-baskets of the extractor begin to drag in the honey, the latter is drawn off and emptied into taps. No strainer is used at any time. It is not necessary with my management.

The next round, two or three days later, brings the whole yard to that state of perfection which I consider ideal in every respect. Every super has sufficient storage to accommodate the incoming nectar, which

controls swarming; and every super, with, perhaps, the exception of a very few of the weakest that have not caught up yet, has honey ready for the extractor, and that enables me to extract whenever I desire to do so.

In the honey-house, conditions are as favorable for the progress of my work as they are outdoors. By the time my tanks are full, or nearly full, the first one has clarified itself and is ready to be drawn off into retail packages. Thus I always have storage for the honey from the extractor, and honey ready to be canned.

During the rush of the honey-flow I make it a point to extract daily, but only during the middle or warmest part of the day. Mornings and evenings I spend my otherwise leisure hours canning. Cleaning, labeling, and filling cans keeps me busy. It takes me about three days to make the circuit; and when the flow is at its best I can begin again at one end when I am done at the other.

In giving the foregoing outline of producing extracted honey, as I practice it, I am well aware that the same management would not suit everybody, nor could it be followed by everybody else; but it is the plan that is best adapted to my own conditions, and I can say I have been quite successful in the past.

La Salle, N. Y.

### THE STARVATION PLAN OF CURING FOUL BROOD.

#### The Infection of the Hive; the Quinby-Jones Plan.

BY G. W. BARGE.

In the summer of 1905 I discovered foul brood in my home apiary as well as in the outyards where my bees were out on shares; and when Mr. France came here he advised using the McEvoy treatment, which we did, but it did not prove entirely successful with us, as the disease appeared again in some hives. We accordingly treated it the next spring. We also tried the Alexander method, with no better results, and, after thinking the matter over, we came to the conclusion that the only way in which the disease spreads is through the diseased honey, so we decided to try a method of our own, which is as follows, and with which we have had complete success.

First, remove the queen; and if she is a good one which you wish to save, put her into a nucleus. After fifteen days look through the hive for queen-cells and destroy all but one to prevent swarming. Wait at least twenty-one days after removing the old queen, as by that time the healthy brood will all be hatched; then take an empty hive, cover the top with wire screen, nail the bottom-board on tight, leaving only the entrance open. Set the hive containing the foul brood a little to one side and put the

empty one with screen cover in the place of it. Shake the bees from the old hive out in front of the entrance of the hive covered with screen. Handle them as quietly as possible, for, the more quiet they are, the less honey they will take with them into the new hive. Lay a sheet of heavy paper in front of the entrance to catch any honey which may drip from the combs when shaking the bees from the frames. (This can then be burned after you are through with it.) It is better to do the shaking in the evening; but we have done the work during the day by using one of the Root hive-tents.

After the bees are all in the new hive, close the entrance and carry them into the cellar or a dark room. I prefer the cellar, as it is cooler, and they will consume the honey which they have carried with them much sooner. Leave them there at least thirty-six hours; then take another hive with good clean combs (I have used full sheets of foundation by giving one frame of brood). Put the new hive on the old stand from which the bees were taken; bring the bees from the cellar, preferably in the evening, and shake them in front of the hive with the combs. The next day examine them to see if they have a queen. If not, always have one ready to give them; but nine times out of ten they will have raised a queen before going into the cellar.

It is surprising how they will go to work after they are brought from the cellar and put into the new hive, and how quickly they will build up. We have had swarms treated in this way during the latter part of May from which we have taken 50 lbs. of extracted honey in the fall, and have never yet found any traces of foul brood in colonies so treated. I call this the starvation plan, and will guarantee it to work everywhere and every time.

In case the swarms to be treated are very weak we take them to a strange yard after removing the queens, and unite two or even three of them by piling up the hives with screens between them and cutting a small entrance in the wooden frame of each screen. After twenty-four hours the screens may be removed, when the bees will all go together without fighting. If there is any honey in the old hive from which the bees were first taken, extract it, then boil it thoroughly, after which it can be mixed with sugar syrup, and fed to the bees when needed. I have fed this honey in the fall for winter stores, and have never found any trace of disease in colonies so fed. Melt the old combs and have the wax made into comb foundation to replace them. Take the covers and bottom-boards off the old hives and nail a strip of wood across the top to hold the frames in; place them in a tank of hot water and boil them. Two minutes of hard boiling is sufficient. After the hives are boiled, put in the covers and bottom-boards and boil them, when all will again be ready for use. We like this plan better than boiling the frames and burning out the hives as given in Scholl's method on page 77, Feb. 1, as in

this way it can all be done at once, and the hives are not charred and dirty inside as when burned. After all is finished you are at no expense except your time, as the extra wax will more than pay for the making of the foundation.

Union Center, Wis.

[The plan here described is practically the same as that advocated by Moses Quinby in the first volume of his book, in 1853. Mr. D. A. Jones, of Canada, some thirty years later, got out a booklet in which he described what he called the "starvation plan." He confined his bees, without brood or combs, in a dark cool place until they had consumed all the honey in their sacs, then let them loose on foundation. But the objection to this starvation plan has been this; It reduces the vitality of the bees. In order to build comb bees ought to be well fed. Indeed, they ought to be fat. To starve them down gives them a bad setback. Experience has shown that bees put on foundation will generally use up all the honey in their sacs in drawing the foundation out into comb, especially if they are made to build comb from foundation twice.

But if foul-broody bees are to be let loose on clean dry *comb*, they should be starved as recommended by our correspondent, and ought to be starved long enough to use up every particle of the honey in their sacs.—  
E.D.]

#### THE ALEXANDER PLAN OF BUILDING UP WEAK COLONIES.

Some Practical and Timely Manipulations; Alexander's Ideas Sound.

BY WM. L. COUPER.

The discussion relative to the Alexander method of curing foul brood should serve to remind us how much bee-keeping lore we owe to the late veteran of apiculture. Speaking personally, my entire system of management has been changed by his writings, though I have frequently varied his plans somewhat to suit my own methods.

I think the first Alexander plan that I tried was his method of building up a weak colony by placing it on top of a very strong one with an excluder between. The first year I tried this it proved a failure with me, though I endeavored to follow his directions exactly. Since then I have employed it continually and most successfully, and I fancy my first failure must have been due to a failure to realize what Mr. A. meant by "a very strong colony." I notice that a good many bee-keepers find it necessary to place either paper or wire screen between the colonies at first. I have never taken any precautions of the kind, and have yet to see the first fight; but my bees are all Italians. About an hour before sundown I remove the cover of the strong colony, replacing it with an excluder. Two hours later I place the weak colony on top, and the job is done.

While this is far the most successful way of building up weak colonies in spring it has some objections. One is that, in dividing the hives after they are both strong, the one that is moved away loses its field bees almost entirely. Another is that bees strongly object to carrying pollen through an excluder, and the combs of the lower hive get choked with it.

#### THE ALEXANDER PLAN FOR MAKING INCREASE.

At one time I used the Alexander plan of making increase throughout almost the entire apiary. I have largely given it up now, partly because I don't want to increase, and partly for other reasons. In case anybody does not know this plan I may say it consists in leaving one frame of brood and the queen in the lower story, and filling up with empty combs or foundation, the other frames of brood being placed above an excluder on top. Queen-cells in the top hive are destroyed in six days, and the tenth day the upper story is moved to a new stand and given a ripe queen-cell—better, a virgin queen; or, best, a laying queen. To beginners who desire to adopt this plan I would offer two suggestions: Do not attempt it unless there is a fair, steady honey-flow, especially if you employ foundation instead of combs. As a rule, the plan will work better if you have two frames of brood below with the queen instead of one. While I do not use this method now for increasing, I do employ it in a modified form for making and building up nuclei and other purposes.

#### NEVER INTRODUCE A QUEEN TO A FULL COLONY.

There was one remark of Mr. Alexander's that I do not think ever received the attention it deserved. It was to the effect that it is always bad policy to introduce a queen to a full colony, for, though she might be accepted at the time, she would very likely be superseded very shortly. If this is the case, and from my own observation I think it very frequently is, should not queen-breeders advise introduction to nuclei?

#### SWARM PREVENTION.

The questions of swarm control and the successful introduction of queens are brought up regularly every season in the bee-journals; so, perhaps, my methods may be of some interest. My swarm-prevention method I discovered by chance. So far it has been successful; but I have not tried it long enough nor on a sufficiently large scale to guarantee it. Give a second story filled with combs as soon as the hive is full of brood, and let the queen have the run of both stories, till shortly before the honey-flow. Then insert a queen-excluder, leaving the queen above. In ten days put her below again. If running for comb honey, remove the top hive in a day or two, and replace with a super (the brood in the top hive may be used to build up weak colonies). I have never found colonies treated like this swarm; but take note that the queen must be left in the top story, as this is important.

Bees do not, in my experience, build queen-cells below an excluder with a queen above, but the reverse way they often will.

Cannington Manor, Sask., Canada.

[It is becoming more and more apparent that Mr. Alexander's teachings stand the test of time when we take into consideration his environment. For thirty years he was almost unknown to the public, and yet one of the most successful bee-keepers in New York. During his latter days he began to write. He had nothing to take back, because his earlier experiences were not down in black and white; and, however much his views may have been modified during his thirty years of actual work, we secured what we may call the final conclusions of his ripest and best experience. Mr. Couper, our correspondent, is not the only one who has been so enthusiastic over the benefits derived from the late Mr. Alexander.

We are pleased to note that Mr. Couper's method of swarm prevention is very similar to one that we used and advocated some years ago. We are prepared to believe it is all right, not that we were the first to give it to the public, but because we had seen it and tested something like it.—ED.]

#### THE LAYING WORKER A RARA AVIS.

Are Workers that Lay as Common as Many Suppose? is Not an Undersized Queen Nearly Always to Blame?

BY ALLEN LATHAM.

To keep bees for twenty-five years, and during that period make a most careful study of their habits; to have the experience which all that entails, and never see a laying worker—well, that raises a question. Scarcely a copy of GLEANINGS comes to hand without some reference to these pests (?), and nearly every mention accompanied by a cure; and the question looms up greater than ever. It loomed so big that I even ventured to state to a friend that I was going to write GLEANINGS and deny the existence of such a thing as a laying worker. The friend, however, checked my enthusiasm thoroughly by stating that he had had lots of laying workers, and that he had even seen the varnints back into a cell and leave eggs.

Once, some twenty years ago, I had what I called a case of laying workers. I called it so because all the signs were there—only drone brood or no brood at all; numerous eggs in cells, and no queen to be found. Since then I have many times found all these symptoms except one, and that one has been persistently absent because a queen was in each case persistently present.

During the last twenty years every summer has furnished numerous cases of colonies, full or nuclei, going queenless. These cases have invariably divided themselves

under two heads—either absolutely queenless or temporarily queenless, the succeeding queen to remain a virgin.

Of the colonies under the first head, colonies have gone queenless in late fall or early winter, and colonies have gone queenless in late spring or early summer. The result has always been the same—no eggs, no brood. No matter how long such colonies were left, in no case have eggs appeared. All colonies showing eggs came under the second head, and every one had a queen.

Why, with so many chances for laying workers to set up their rule, have none ever appeared in these colonies? Is there any answer other than the title which heads this small article—the laying worker is a rare avis?

One is led to think that, in all probability, the vast majority of cases of so-called laying workers are cases of undersized virgin queens. That one painstaking observer should not find a true case in twenty years, though he had scores, if not hundreds, of apparent cases, should not be considered a circumstance to be lightly passed over. The actual finding of worthless queens is better evidence than the failure to find any queen.

During the past summer I had one or two rather annoying cases. For a time I began to suspect that no queen was present. It was only after persistent search, a search which called into play all my skill, that I eventually in each case spotted the insignificant queen. The removal of each queen was followed by an easy introduction of a good queen.

Though I do not deny the existence of laying workers, I am forced to think that they have been given credit for being much more common than they are, and for being, in consequence, of much greater importance than they are. I firmly believe that more careful search will, in the majority of cases of laying workers, reveal what the bees recognize as a queen, but what is easily overlooked by the bee-keeper because she has not every attribute of a queen.

Much greater care must be exercised in the search for this queen than in the search for a normal queen. Queen and bees both fail to act in a perfectly normal manner. The queen is more inclined to hide than is the sound queen, and the workers are less inclined to indicate to the bee-keeper the locality of the queen. Though the queen is recognized as a queen, she gets little homage.

The best way to find such a queen is to proceed as follows: Open the hive gently, and quietly remove combs from both sides. Before removing any combs it is also well to lay a strip of cloth lengthwise over the combs containing the eggs and brood. Continue to remove combs from each side till only two are left. If careful selection has been made, these two will, in the vast majority of instances, hold the queen. Now split these two combs apart with a quick motion, and give a rapid glance over their inner surfaces. If the queen is not seen inside of ten seconds, replace these two combs; but either

leave the others outside, or, if placed in hive, leave them two or three bee-spaces away from the central two. In about fifteen minutes take another look between those inner combs.

Do not look for a plump queen which moves majestically about the frame, nor one which slides with folded wings quietly under the bees. Look rather for a nervous bee with wings partly outspread, a bee somewhat larger than a worker, but with actions unlike those of a worker. When one knows what to look for, these small flighty queens are nearly as easy to find as are the normal queens.

One strong argument in favor of the belief that laying workers are of rare occurrence lies in the fact that nearly every remedy, if not all, will as certainly get rid of such a queen as I have described. The queen is never found, and this is usually accepted as sufficient evidence that there existed a bona-fide case of laying workers.

It has been suggested that laying workers are evidence of Cyprian blood. As the writer has been in the habit of sticking to bees with a goodly percentage of black blood, his failure to find laying workers may be thus easily explained. It might be worth while to gather more complete data along this line. If there are apiarists who have had laying workers of other than Cyprian or Golden stock, why not hear from them? But let proof be offered. Failure to find a queen is no proof at all. Some of these little queens go through excluder zinc quicker than you can say Jack Robinson. The only satisfactory proof is to catch a worker in the act of laying an egg. One can divide a colony of supposed laying workers; and if eggs continue to appear in *both* portions, this is fair proof.

Norwich, Conn.

[While we believe laying-workers are uncommon we are sorry we can not agree with our correspondent on another point. There is a wide difference between the work of dwarf or scrub queens and that of laying workers. In a well-regulated apiary, especially where its owner keeps up with the times, laying workers, or the evidence of their work, is very rarely found. In fact, we are almost inclined to think that almost any one who allows such pests to develop among his bees is not much of a bee-keeper. One of two things is true—he is either careless or ignorant.

Every queen-breeder is very familiar with these scrub or dwarf queens. Some of them are so small that they are very difficult to find. They are not a rare bird in a large queen-rearing yard. But one thing is sure—it is quite impossible to introduce a queen, laying or virgin, to a colony having one of these worker-like queens. On the other hand, it is quite possible to introduce a laying queen or virgin in a hive of laying workers. To give a ripe cell is the usual remedy for the nuisance. We never, in all our experience (and we have raised thousands of queens) seen a case where a scrub queen

would scatter eggs like a laying worker unless she were somewhat cramped for egg-laying room.

The very fact that Mr. Latham, a progressive bee-keeper, has not found laying workers among his bees is not at all strange. He ought not to find them. Most strains of bees can be queenless a considerable length of time without developing laying workers. We will venture to say if he or any one should attempt to produce them by making a hive long queenless he would be disappointed. He might succeed with the Eastern races. It is very seldom that we have laying workers in any of our yards; and when they do show up we are sorry to confess it is in the case of a yard that has been neglected. We have, around Medina, in our various yards anywhere from four hundred to six hundred colonies. Among all these bees we do not have a hive of laying workers once in three years, notwithstanding that some hives will be long queenless some time in the spring when the demand for queens is heavy and it is too early to give cells or virgins; but scrub queens from some insignificant cell that escapes scrutiny are not uncommon. Such queens make all kinds of trouble until they are located and their heads pinched. If Mr. Latham keeps only a limited number of colonies it would not be surprising if he should not find a case of laying workers in thirty years.—ED.]

## COMB AND EXTRACTING SUPERS ON THE SAME HIVE.

### A Plan for Preventing Swarming, and Inducing the Bees to Enter Comb-honey Supers Readily.

BY JAY SMITH.

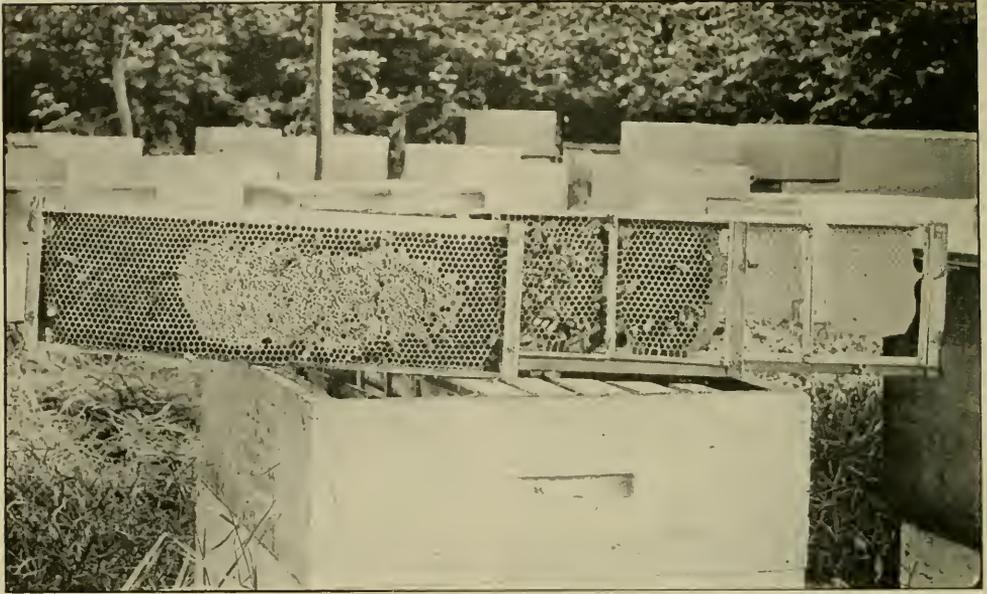

The question is frequently asked, "What is the best-sized hive for comb honey?" The answer has usually been that the eight-frame L. hive or the ten-frame Danzenbaker is recognized as the proper size. Others contend that these hives are too small for a prolific queen to lay to her full capacity and yet have room in the hive for ten or fifteen pounds of honey and a frame of pollen which are necessary for the best results. Now, both of the above claims are entirely correct; but it will be seen that, if the same size of hive is used for brood-rearing and for comb-honey production, you can not have the advantages of both the large and small hive. I wish to state here that the person who uses one size of hive for both purposes is not getting out of his bees what he should.

Some time ago I described in GLEANINGS how I used two hive-bodies for brood-rearing and then reduced to one for the honey-flow. This system was good; and when it came to getting a host of bees on deck at the critical moment it worked to perfection. But it had several drawbacks when running on a large scale. When it came time to put on supers it was a job to open hives and put all brood in one body. And then some of the hives I took off had brood in them. This had to be looked after. Then a lot of the honey in these extra bodies was unsealed honey. This had to be put on a hive or it would have soured.

The system I have used for two years back has all the advantages of the above, and none of its disadvantages. Instead of using two full hive-bodies I use one Danzenbaker hive and a shallow super filled with extracting-combs. When raising brood before the honey-flow this super is on the hive, and the queen has full sway, and can lay in the hive-body or upstairs as her royal highness wills. Now, the swarming season comes on just after the flow starts; and unless one has plenty of room for the queen to lay, as well as room for honey, swarming will be the result. But leave this on shallow extracting-supers till the bees are busy gathering, and then raise it up and put the comb-honey super on between the extract-

ONE OF JAY SMITH'S HIVES, SHOWING EXTRACTING-COMBS AT THE SIDE OF THE SUPER, A LA TOWNSEND.

THEY WORK WELL STARTED IN THE EXTRACTING-COMBS AT THE SIDE OF THE COMB-HONEY SUPER.

Note that the row of sections just back of the extracting-frame is also well along, and that the second row back is started.

ing-super and hive. As will be seen, this gives more room right in the middle of the brood-nest; and instead of cramping the bees, and forcing them into the supers and forcing swarming when the super is added, it really gives more room and checks swarming. The bees will at once begin drawing out the foundation; and as soon as this is nicely begun, the comb-honey super should be brought on top of the extracting-super, or there will likely be pollen and possibly brood in the sections. After this is done, a queen-excluder should be put next to the hive-body or the queen will again occupy the extracting-super. In a short time all the brood will be hatched in the extracting-super, and it will be filled with honey, and capped. It should then be removed and extracted. The comb-honey super will have work well advanced, and this is then placed next to the hive, where it will be finished in a hurry without any light-weight sections.

As soon as the flow is over, the empty extracting-super is placed on the hive again, and the queen at once fills it with eggs. If the prospect is good for a fall flow, the above plan is again carried out. If not, they are left just as they are all winter. The super is filled with dark honey, and the bees arrange their nest for winter. They usually form their cluster so that the space between the super and hive-body comes right in the center of the cluster. This gives them the best of communication with each other all winter. They also have a lot of honey so they will not be stingy with it when they need it for brood-rearing in the spring.

I see some writers think that bees rear brood just the same whether they have one pound of honey ahead or twenty-five. It seems strange to me that they would accuse the bee, that is considered the most intelligent of all insects, of raising a lot of young bees to use up the last drop of honey and then starve to death! I know from experience that they very carefully keep account of the stores ahead, and raise brood accordingly; and with plenty of comb space and honey it is surprising what they will do in the way of bringing a lot of bees on the scene just when they are needed.

I wish to protest against another statement that has been made several times, although I can not recall when. Several have said that if one extracts from black brood-combs the honey will not be as white as from new white combs. My experience proves to me that there is no ground for that statement. I will give one of my experiments. I picked out ten of the blackest brood-combs that I could find, extracted the honey, and put it in glass jars. Then I thoroughly cleaned the extractor, and extracted from ten new combs as white as snow. I set these jars with the others; and when I went to compare them I was unable to pick the last ones out of the lot. I compared the color and tasted of the honey, but could see no difference.

I have been using Mr. Townsend's plan of putting extracting-combs at the outside of the sections, and feel that in this Mr. Townsend has given the bee fraternity a most valuable kink. In the engraving will be seen a super just set on the hive. The bees

immediately take possession to clean it up. They will at once go to work and store honey in the comb. The other picture shows the work as it progresses. The outside extracting-frame is partly capped. The comb-honey section next to it has honey in it, while the third has work just commenced. After the bees begin in the center ones they will push the work there a little faster, with the result that the entire super is finished at once and can be set aside for market without sorting.

I am running eighty colonies on this plan this year, and I have never had a single case of loafing, and the bees work with all the energy they possess. When I read of some who let the hive-body get clogged with honey, and the bees cluster out, and they "shake" energy into them, I thought the bee-keeper was the one who needed shaking instead of the bees. With the above system I usually have about six per cent of swarms. This was the worst year for swarms I ever had, and the per cent of swarms was ten.

Vincennes, Ind.

#### AN OPEN-AIR COLONY IN MICHIGAN.

BY A. H. GUERNSEY.

On Sept. 6, 1909, hanging on a limb  $1\frac{3}{4}$  inches in diameter and 43 feet from the ground, I found a large swarm of bees which, without protection, had built combs two feet long and 13 inches deep. The combs were all covered with bees, and at first sight they resembled a young bear hanging with his back down. Two weeks later I went with my spring wagon, extension ladder, box, ropes, etc., to get it. I went up the tree, roped the limb properly so it would hang when cut off just as it was before, then sawed it off, and from where I stood lowered it slowly until it was near the ground. I then fastened my rope securely and went down. I placed a sheet of cheesecloth under the bees, wrapped it up snugly to the cluster, and tied it around the limb at both ends of the combs, so that no bees could get out; then cut the limb a little beyond the combs at each end. I put the whole thing in a large box and took it home, 13 miles, with the loss of but very few bees.

After I had the picture taken I gave an exhibition

on the streets and at several homes, and but few bees were lost.

I expect to hang this swarm out on a tree in the open as a curiosity. I never saw a colony before in Michigan that would thrive and do well without protection. In a warm climate, of course it is a common thing.

Ionia, Mich., Dec. 10.

#### CREATING A DEMAND FOR HONEY.

How the Bee-keeper can Direct the Attention of the Public to his Honey.

BY FRED WULF.

There is no one better adapted to the work of helping the local market and creating a demand for honey than the bee-keeper himself. I have been selling and peddling my honey for the last six years, and find it the

A. H. GUERNSEY'S HIVELESS COLONY.

FRED WULF'S HONEY DISPLAY IN A GROCER'S WINDOW DURING A CARNIVAL IN SONORA, CAL.

only way to get honey properly before the public. As some of us know, the returns are often very small when we ship honey into the large cities and leave it in the hands of the commission merchants. With some effort on our part we can easily sell our crops at home and get the best prices.

Well do I remember how hard it was for me, when I first started, to enter into the spirit of talking and get courage enough to go from house to house and show what I had to sell. Now I have a route established so that I know just where to go, and I am selling more than three times the amount that I sold at first. Question after question asked—where the honey is produced, the reason why extracted honey is less in price, whether it is pure, etc. Some of these questions may be answered by the bee-keeper; but when it comes to making a general explanation, which I have found often takes fifteen minutes or more, I make use of the little leaflets entitled "The Food Value of Honey." Some people will keep on talking for a long time, and one of these leaflets is just the thing to hand to them.

I also get the storekeepers started. This I find as important as going out myself and peddling, for as a rule the merchant puts the honey on the shelf out of the way, and his customers see nothing of it, especially if it is *comb* honey. I always try to have the honey placed where it will be seen. This greatly increases the sales.

Occasionally I succeed in getting some merchant to make a display in the window, and this pays a big profit. Last fall during a carnival in Sonora, Cal., which lasted a week, I made a very attractive display of

an observatory hive of bees, and a house built entirely of comb honey. This attracted so much attention that the newspapers took it up. For instance, here is what the *Sierra Daily Times* had to say:

#### A HONEY HOUSE.

The honey house in the show-window of Michel's store is a wonderful thing, and should be seen by everybody. The frames of which it is composed, sides and roof, are of honey in the comb, unbroken and perfect. It is the work of F. Wulf, of Yankee Hill, and should be shown at the Portola as a Tuolumne Co. production.

Another paper had a picture of the honey house similar to the one shown in the accompanying engraving. The sections on each side were placed there to fill it out better. As the house stood in the show-window I had a round pyramid at each side. Over the door or entrance of the house I placed one of my regular honey-labels, on which were the words "Pure Honey from the Apiary of Fred H. Wulf, Columbia, Cal."

Columbia, Cal.

#### BEE-KEEPING IN TENNESSEE.

BY A. L. BOYDEN.

If bee-keepers of the North, where white clover and basswood are abundant, or those bee-keepers of the great honey-producing States in the West, where the alfalfa and sage produce such wonderful yields, have an idea that the production in the South is insignificant, a visit to some of the leading fairs and expositions, notably those of Nashville, and Dallas and San Antonio, Texas, would correct such an impression. We read in the last census that about ten per cent of

the farms in the North Central States report bees while thirteen per cent in the South Central States keep them, and the number of colonies in the South Central States is considerably greater than the number of colonies in the North Central States. The number of pounds of wax produced in the South Central States was at least 50 per cent greater than in the North.

We read in the same report that the three most important States at the time the last census was made,

taking the number of colonies as a basis, were Texas, North Carolina, and Tennessee.

It is true that, ten years ago, the careful attention was not given to the bees in Tennessee that was found in many other States; but, due to the efforts of the Tennessee Bee-keepers' Association, a marked difference will be found in the report of the present census.

At the time of the last report, the State was credited with a total of 225,788 colonies, and the average in each county seems to be

2000 colonies. A few counties showed as many as 4000 colonies, and but few fall below 1000 colonies.

The efforts of the Tennessee Association, and of the superintendent of the apiarian department, Mr. J. M. Buchanan, have resulted in a most creditable display of honey, bees, and bee-keepers' supplies at the Nashville fair for several years past. The daily papers, in speaking of the display, spoke most favorably indeed of it last October, commenting on the fact that it was one of

APIARY OF J. M. BUCHANAN, FRANKLIN, TENNESSEE.  
Mr. Buchanan is regarded as a very successful apiarist.

ONE OF THE QUEEN-REARING APIARIES OF J. M. DAVIS, SPRING HILL, TENNESSEE.  
Queens from this yard are known the world over.

EXHIBIT OF J. M. BUCHANAN, FRANKLIN, TENN., AT TENNESSEE STATE FAIR, NASHVILLE, OCTOBER, 1909.

the most attractive exhibits on the grounds. As usual, the number of exhibitors was not large; it seems to be this way at most of the fairs, even where a liberal premium list is found. It is somewhat to be regretted that more bee-keepers do not interest themselves in making exhibits, for, even though the premiums awarded will scarcely pay for the time and labor expended, it must be remembered that in no other way can such an opportunity be found for educating the public regarding the use of honey.

Due to the efforts of the exhibitors and superintendent, a very fine general exhibit was found last year in the Agricultural Building at Nashville; and by the efforts of these same men and the Tennessee Beekeepers' Association, the Tennessee State Fair has adopted quite a model premium list. It is none too early for bee-keepers to begin to lay their plans for fall exhibits. A list of premiums awarded will, we believe, be of interest to readers, not only in Tennessee but in other States.

The following awards were made:

- Best 10 lbs. of extracted honey in glass.  
 First premium, J. M. Buchanan, Franklin, Tenn.  
 Second " N. O. Walker, Franklin, Tenn.  
 Third " R. D. Buchanan, Franklin, Tenn.  
 Fourth " J. J. Reams, Franklin, Tenn.
- Best display of extracted honey, 50 lbs. or more.  
 First premium, N. O. Walker.  
 Second " J. M. Buchanan.  
 Third " J. J. Reams.  
 Fourth " Ira A. Moore, Nashville, Tenn.

- Best case of comb honey, 12 lbs. or more, quality and appearance to count.  
 First premium, J. J. Reams.  
 Second " J. M. Buchanan.  
 Third " R. D. Buchanan.  
 Fourth " N. O. Walker.
- Best display of comb honey, 50 lbs.  
 First premium, J. M. Buchanan.  
 Second " N. O. Walker.  
 Third " J. J. Reams.  
 Fourth " Ira A. Moore.
- Best 5 lbs. of granulated honey.  
 First premium, R. D. Buchanan.  
 Second " J. M. Buchanan.  
 Third " N. O. Walker.  
 Fourth " J. J. Reams.
- Display of labeled samples, showing honey from different kinds of flowers.  
 First premium, J. M. Buchanan.  
 Second " R. D. Buchanan.  
 Third " N. O. Walker.  
 Fourth " I. A. Moore.
- Best half-gallon of honey vinegar.  
 First premium, I. A. Moore.  
 Second " W. M. Joseph, Nashville, Tenn.  
 Third " J. M. Buchanan.  
 Fourth " B. J. Fox, Nashville, Tenn.
- Best display of beeswax, 25 lbs. or more.  
 First premium, N. O. Walker.  
 Second " J. M. Buchanan.  
 Third " R. D. Buchanan.  
 Fourth " J. J. Reams.
- Nucleus of dark Italians.  
 First premium, J. M. Davis, Spring Hill, Tenn.  
 Second " B. J. Fox.  
 Third " N. O. Walker.

We believe Mr. J. M. Buchanan is again superintendent of this department; and while the premium list for 1910 may not yet be printed, it will undoubtedly be much the same as the above list for 1909, and information can doubtless be secured by addressing him. Bee-keepers who can do so should by all means encourage the superintendent and the State Fair Board by putting up a splendid exhibit the coming fall.

### A BALKY SWARM.

BY EDW. T. MURRAY.

I am sending a photograph of a balky swarm that one of my neighbors had last June. This was the second swarm that issued from an old Langstroth hive. The bees started to build comb on the outside of one of his empty hives. Later on they commenced work in frames that were inside the hive.

Torresdale, Pa.

A SWARM THAT INSISTED ON BUILDING COMBS OUTSIDE THE HIVE.

### OBSERVATIONS ON SPRING STIMULATIVE FEEDING.

When Bees Can Not Fly in the Spring, Stimulative Feeding is a Waste of Energy.

BY F. DUNDAS TODD.

That title is not right. You see I did not do any stimulative feeding at all, but I made a few observations which gave me food for thought, and I want to tell my conclusions to other people.

Most bee literature written on this continent is naturally from men who live in average regions; but the climate in this outpost is so different that we see things differently. It was somewhere in the Middle States that a little girl once said, "Just as soon as it gets warm enough to do anything it is too hot to do anything," which, by the way, is a rather neat way of expressing the sudden jump from winter to summer in most parts of the United States. In this part of the world, summer creeps upon us; one bee-keeper says spring here is a long-drawn-out agony. This year we had ten glorious days in the first half of March when the bees rushed in pollen at a tremendous rate; then for three weeks the weather was so cool, cloudy, or wet that hardly a bee left the hives. It may be safely said that, during that period, not a snap of pollen nor a drop of nectar was carried in.

On looking over the colonies on March 12 I found about a third of them rather short of stores, so I gave these a pint each of syrup, and no more have they had up to date. The very strongest colony was *in extremis*, living from hand to mouth; but it got to be the same as the rest. I had to go out of town immediately, so for a month the bees were run on the let-alone plan.

Now for the observations. In the middle of January I examined a hive, finding in one frame a patch of eggs that covered a space slightly larger than a dollar. On March 2 pollen began to be carried in, so on the 12th I overhauled every hive and found brood in every one that was queenright, ranging from two to four frames. The strongest hive, but a weak one in stores, had brood in two frames only. It was evident that egg-laying had started with the advent of pollen.

The next examination was on April 17, eight days after flight had been reestablished, and on this occasion I found that, with only six exceptions, the frames containing brood corresponded almost exactly with the number on March 12. Furthermore, as none were sealed the eggs must have been laid after the resumption of flight a week previously. The hustling queen had extended from two to six frames, leading the procession; yet in the matter of stores this colony was in bad shape, but strong in bees. The hive best provided with supplies, one of fair strength, had made no headway at all.

Here, then, is the noteworthy feature.

Brood-rearing, this spring at least, depended entirely on one fact. When flight was free the queen got busy; when it stopped, so did she. There was no question of pollen-dearth, as there was plenty of old pollen in the hives.

It is doubtless a good thing to have "millions of honey in the house" in spring; but when the bees can not fly, apparently they do not care to use it. So far as I can draw conclusions from this season's observations, I would rather have thousands of bees than millions of honey.

The principal conclusion I have arrived at is this: When bees can not fly, spring stimulative feeding, whether of sugar syrup or artificial pollen, or both, is a waste of energy.

I am aware that one swallow does not make a summer; neither is it safe to generalize from one season's observations; but, nevertheless, those made in a climate that is different from most are, I feel, deserving of record.

Victoria, B. C., April 26.

## THE ESTABLISHMENT AND MAINTENANCE OF A BROOD-CHAMBER.

### Eight vs. Twelve Frame Brood-chambers.

BY R. F. HOLTERMANN.

*Continued from last issue.*

In my experience with bees and the brood-chamber of the hive they occupy, I find certain conditions which govern. If I wish to establish a brood-chamber, there are conditions which have a bearing on that question. 1. The distance apart the frames are spaced; 2. The nature of the comb foundation used; 3. The number of bees with which it is established; 4. The amount of brood when a heavy flow begins; 5. The queen.

Now, I do not profess to name these in the order of importance. Such would seem to me to be something like solving the foolish problem often propounded—which is the most important, the hive, the locality, or the man? when any one of them left out would leave no problem.

1. The distance of spacing is important, I feel sure. Let me illustrate: In a super, combs may be spread so that ten combs occupy the space twelve normally do. But when foundation is used, bees come up, occupy, and build on that foundation much more readily when the spacing is normal than when it is abnormal. I use a brood-chamber spacing 17 inches inside the hive for 12 frames, using no follower, yet I am not prepared to say that slight variations from this will work any injury.

2. As to the foundation used, Jacob Alpaugh first directed my attention to this point, and I will give his words as nearly as I can recall them. He stated, "There are lots of queens condemned as not up to standard for laying, because the combs do not suit them. There are makers of foundation who, in the process of making, stretch the cells so that they are larger one way than

the other, or the foundation may be stretched in the hive through no fault of the foundation-maker. When this foundation is built out, the queen, from natural instinct, does not care to use them, and she loses much valuable time because she does not have suitable cells to lay in."

I heartily endorse this statement; and if the queen is to do her best, do not condemn her without a fair trial. The bee-keeper, not the queen, may be to blame.

3. In establishing a brood-chamber the nicest drawn-out comb can, as we almost all know, be secured by giving the bees no more room than they can well cover and draw out at one time. Bulging and uneven sections in supers, for instance, are often the result of too much room for the conditions which prevail when the comb is built out. The same holds good in a brood-chamber.

4. I aim at getting the brood-chamber well filled with brood before any thing like a heavy surplus honey-flow begins. With a good flow it is the tendency of the bees to fill all unoccupied space about the brood with honey, thus in a measure shutting off the opportunities to expand the brood-nest. True, some varieties of bees and some strains in perhaps all well-known varieties, will overcome this by prolific queens that either, by their own manifest energies or by that in combination with a trait in the worker bees, seems to gain ground with the brood and crowd the honey into the supers; but this process means a loss of time, and therefore lost worker bees later in the surplus honey-flow or for winter. For the same reason I avoid, in the honey-flow, taking combs of brood out of the brood-chamber and putting in their place empty comb, as, with a good strong honey-flow, these are often filled with honey.

For this reason, if a man has an eight-frame Langstroth hive, and he changes to a twelve-frame just at the commencement of a honey-flow, he may not get satisfactory results unless he has very prolific queens or a long honey-flow. He may even, unless he considers the honey in the brood-chamber, have a poorer honey crop. He can take a good eight-frame colony and add combs as wanted before a heavy flow; but with a heavy flow the bees may fill the added comb largely with honey. Where a bee-keeper establishes a large colony, goes into winter quarters with a twelve-frame colony instead of an eight-frame, and winters them well, he can then win out alongside of an eight-frame stock wintered equally well, and do it with less fussing and manipulation. If for any reason the colony lags in brooding or building up, as some may, no matter what the kind of hive, he can contract until a suitable opportunity offers for expansion.

5. The queen has already been referred to so often that nothing more need be said on this point.

In closing, let me say that the method of manipulating the supers has a bearing on
